Treatment

INTRODUCTION

The one generalization about *venous thromboembolism* (VTE) that is free from controversy is that many aspects of this disorder remain controversial. There are multiple reasons why VTE continues to engender lively debate. Perhaps the major reason, notwithstanding the substantial advances that have been made since the late 1990s, is that a number of fundamental questions continue to exist regarding the pathogenesis, clinical presentation, diagnosis, and therapy of the disease.

VTE represents a potentially fatal disease process with a clinical presentation that is often silent or nonspecific and for which a wide range of diagnostic techniques is available, many with technical and interpretive limitations. Although estimates vary widely, the best available information suggests that there are at least 5 million episodes of venous thrombosis annually in the United States.¹ The annual incidence of acute *pulmonary embolism* (PE) is approximately 70 per 100,000,^{2,3} and PE accounts for more than 200,000 hospital admissions per year on the basis of discharge diagnosis (ICD-9) codes.⁴ These data, of course,

Schistosomiasis

Air Embolism

Fat Embolism

Amniotic Fluid Embolism

Septic Embolism

Other Emboli

represent only those patients in whom the diagnosis of acute PE was made correctly. Autopsy series suggest that the true number of deaths from acute PE (including those patients who died without the diagnosis ever being made) is at least threefold higher.⁵⁻⁸ For this reason, it is likely that the majority of PE-related deaths can be attributed to PE that was undiagnosed (and therefore untreated) during life.

Up to 10% of patients who suffer embolism may die from their disease.⁹ The overwhelming majority of these deaths do not appear to arise from therapeutic failure. With the exception of patients who initially present with hemodynamic impairment, in whom mortality rates approach 20% to 30%, embolic recurrence is rare and death is uncommon once the diagnosis of embolism is confirmed and appropriate therapy initiated.¹⁰ The majority of deaths related to embolism appear to arise from a failure to prevent the disease in patients at risk of it and from a failure to make the diagnosis in those afflicted.⁹ The incidence of fatal PE appears to have declined over the past several decades.^{11,12} For example, the Centers for Disease Control *Compressed Mortality File* (CMF) reported an age-adjusted death rate of 875/100,000 in 1999, which steadily decreased over the decade to 747/100,000 by 2010.¹³ It is noteworthy that these statistics do not account for fatal PE that was undiagnosed clinically, as described earlier. Balancing these facts are some data that suggest that the increasing reliance on chest *computed tomography* (CT) angiography may be leading to overdiagnosis of PE in some populations.¹⁴ Despite this controversy, mortality from acute PE remains a substantial public health care problem as a result of the demographics of an aging population.¹⁵

Contributing to the debate surrounding VTE is the involvement of a wide range of medical disciplines in its prevention, diagnosis, and management. Thrombosis is not a discrete clinical subspecialty. The problem of VTE involves pulmonologists, cardiologists, hematologists, internists, specialists in vascular disease, radiologists, a range of surgical subspecialists, obstetricians, and others. Because specific prophylactic, diagnostic, and therapeutic strategies within one discipline may not necessarily be applicable to another, a perception of coherence in the clinical approach to this disease process often appears to be lacking.

Many of the long-standing controversies surrounding the natural history, diagnosis, and therapy of VTE have been partially or completely reconciled, resulting in substantial changes in the diagnostic and therapeutic approach to the disease. The persistence of a number of unresolved issues, as well as the emergence of still others, should not be a cause for cynicism. In the approach to the patient with suspected VTE, an understanding of what is unknown can prove invaluable to the decision-making process.

PATHOGENESIS AND RISK FACTORS

The triad of venous stasis, alterations in coagulation, and vascular injury identified by Virchow in 1856 as primary factors in the pathogenesis of VTE has been supported by a considerable amount of clinical and experimental evidence. Over the past several decades, severe abnormalities of the

Lupus anticoagulant
Inflammatory bowel disease
Paroxysmal nocturnal hemoglobinuria
Behçet syndrome

coagulation and fibrinolytic system, including isolated deficiencies of antithrombin III, protein C, protein S, and plasminogen, as well as the presence of a lupus anticoagulant, have been described and their association with first-time and recurrent VTE has been confirmed (Table 57-1).^{16,17} In addition, there has been increasing recognition of less severe, but more common, inherited “thrombophilic” conditions that are capable of shifting the hemostatic balance toward thrombosis and mildly increasing the risk of venous thromboembolic events. Although they also appear to increase the risk of recurrence slightly, the magnitude of the increase is unlikely to warrant changes in therapeutic strategies for patients with those thrombophilias.¹⁸

The most common of the inherited thrombophilic conditions, first described in 1993 by Dahlback and designated *factor V Leiden mutation*, is the consequence of a single point mutation in the factor V gene (adenine for guanine) resulting in activated factor V (factor Va) with diminished sensitivity to the natural anticoagulant effect of activated protein C.¹⁹ Approximately 5% of whites in Europe and North America are heterozygous for this genetic defect; lower rates of carrier frequency have been reported among Native American, African, and Asian populations.^{20,21} Although initially detected in up to 60% of selected patients with VTE, subsequent studies have detected the mutation in 10% to 20% of unselected patients.²² The heterozygous state carries a 5- to 10-fold increase in lifetime risk for VTE.^{23,24} Whereas

the relative risk among patients homozygous for this mutation has been estimated to be as high as 80-fold, the estimates are based on a small number of patients and may be somewhat imprecise.^{23,24} Factor V Leiden mutation appears to be an important risk factor for VTE during pregnancy, in the postpartum period, and during oral contraceptive use.^{25,26} Compared with women who do not use oral contraceptives and are not carriers of the factor V mutation, the risk of thrombosis among those with both risk factors is increased approximately 30-fold.²⁷ In view of the prevalence of thrombophilia and the low prevalence of VTE in nonusers of combined oral contraceptives, the absolute risk remains low. Because the absolute increase in VTE is modest, selective thrombophilia screening based on previous personal or family history of VTE is more cost-effective than universal screening.

A sequence variation in the prothrombin gene (G20210A) was described in 1996 and is estimated to exist in approximately 2% to 4% of the population.²⁸ This mutation results in an overproduction of prothrombin, which is otherwise normal. It is associated with a threefold to fourfold increased risk of lower extremity venous thrombosis.^{28,29}

Hyperhomocysteinemia has also been identified as a potential independent predisposition to VTE. Elevation of plasma homocysteine levels may be the result of genetic abnormalities; nutritional deficiencies of vitamins (B₆, B₁₂, folate); clinical disorders (renal insufficiency, hypothyroidism, inflammatory bowel disease); or a combination of the three. Although retrospective, case-control studies demonstrate an association between hyperhomocysteinemia and VTE, the results of prospective studies have not been uniform.^{30,31}

The three “common genetic thrombophilias” (factor V Leiden, prothrombin G20210A, and hyperhomocysteinemia) appear to act as independent risk factors for increasing thrombosis risk.^{32,33} Thus, the relative risk for patients with multiple thrombophilic conditions is higher than for patients with only one of them.

The identification of these risk factors, and the likelihood that others exist, raises the possibility that screening to determine relative thromboembolic risk may be feasible in the future. However, a consensus for such an approach does not exist at the present time. Despite its prevalence in the general population, screening for factor V Leiden mutation is not advised because the overwhelming majority of patients with this abnormality will never suffer a thromboembolic event. Furthermore, the absence of this abnormality should not influence the decision to provide prophylaxis to patients at clinical risk. In addition, there is no evidence that prolonged anticoagulation would be more beneficial for VTE patients with either factor V Leiden³⁴ or the prothrombin G20210A gene³⁵ than in VTE patients without these mutations.¹⁸

Patients with spontaneous (“unprovoked”) VTE who have *both* factor V Leiden and the prothrombin G20210A gene³⁵ appear to be at somewhat higher risk for recurrence than similar patients without those mutations. This observation does not establish a risk-benefit relationship for prolonged anticoagulation in patients with the combination of thrombophilic mutations, which remains unknown.

For all the reasons stated previously, the benefit of screening for the common thrombophilias is controversial. Patient

groups in whom screening is likely to yield positive results include those with a history of recurrent VTE or with a confirmed family history of thromboembolism, a first episode of thromboembolism at an early age, spontaneous venous thrombosis, thromboses in unusual anatomic sites, arterial thrombosis, and thromboembolism associated with pregnancy^{36,37} or estrogen use. Whether screening should be performed before the initiation of oral contraceptive agents remains a matter of debate.^{38,39} The relative risk of VTE is increased approximately fourfold in users of oral contraceptives, although the increase in absolute risk is modest.^{27,40} A policy of routine screening would deny effective contraception to a substantial number of women while preventing only a small number of PEs. A similar situation exists for pregnancy, in which the presence of factor V Leiden or the prothrombin G20210A mutation increases the relative risk of VTE but only slightly increases the absolute risk.³⁷

In most patients, even those with an identified thrombophilic state, clinical conditions associated with venous stasis, intimal injury, or both serve as the basis for the thromboembolic event.⁴¹ Furthermore, the risk of VTE in hospitalized patients is not limited to patients undergoing surgical procedures. Thromboembolic risk in patients admitted with a wide range of acute medical problems is comparable with that seen in surgical patients.⁴²⁻⁴⁴

Major risk factors include pelvic or lower extremity fractures, hip and knee surgery, a past history of VTE, acute paralytic stroke or spinal injury, major traumatic injury, open prostatectomy, and abdominal or pelvic surgery for malignant disease. Other factors that enhance risk include prolonged general anesthesia, advancing age, cardiac disease, pregnancy,³⁶ the postpartum state, the use of estrogen-containing hormone replacement therapy,⁴⁵ malignancy, nephrotic syndrome,⁴⁶ the presence of a lupus anticoagulant or antiphospholipid antibody, and prolonged immobilization.⁴⁷ Air travel is a relatively modest risk factor,⁴⁸ as is the presence of inflammatory bowel disease.⁴⁹ It is important to recognize that these risk factors may be multiplicative.^{37,41} Thromboembolic risk in an otherwise healthy 45-year-old individual undergoing an elective cholecystectomy is considerably less than the risk experienced by an obese 75-year-old with a history of prior VTE undergoing the same procedure. Similarly, the patient with hip fracture or hip replacement has, by virtue of that condition alone, a 60% to 70% risk of *deep venous thrombosis* (DVT) and a 2% to 4% risk of experiencing a fatal thromboembolic event in the absence of preventive measures. Add other risk factors, as well as the incidence of DVT, and the likelihood of a fatal complication will be even higher. These considerations allow the development of a reasonable “risk profile” in an individual patient, a profile that should influence the use and intensity of prophylactic intervention.⁴¹

NATURAL HISTORY: DEEP VENOUS THROMBOSIS

Venous thrombi appear to originate either in the vicinity of a venous valve cusp, where eddy currents arise, or

at the site of intimal injury.⁵⁰ Platelet aggregation and release of mediators initiate the sequence. With local accumulation of such factors, the coagulation cascade is activated and thrombus develops, composed primarily of fibrin and erythrocytes. As the thrombus extends, local fibrinolytic activity is enhanced. Thus thrombus behavior becomes a dynamic process that may result in complete dissolution, partial resolution resulting in a variable degree of intimal narrowing and valvular damage, progressive proximal extension, or embolization. In more than half of patients, the venous wall suffers some degree of permanent scarring, which is visible on ultrasound⁵¹; if the venous wall scarring causes severe obstruction, collateral veins develop.

Extensive autopsy and clinical studies have established that some 90% of PEs that elicit clinical attention arise from venous thrombosis in the deep veins of the lower extremities.⁵² In fact, a conservative estimate is that at least one third of deep venous thrombosis is complicated by symptomatic or asymptomatic PE.⁵³ Venous thrombi capable of embolization can also arise from other sites. Primary iliac or proximal femoral thrombi may develop in patients undergoing surgery involving the hip, and pelvic vein thrombosis may develop in patients undergoing pelvic or prostatic surgery. Axillosubclavian vein thrombosis may be spontaneous, resulting from congenital abnormalities of the thoracic outlet, or may be related to indwelling central venous catheters, pulmonary artery catheters, or transvenous pacing wires.^{54,55} Increasing use of central venous catheters has been implicated in a rise in the incidence of upper extremity deep venous thrombosis.⁵⁶ In patients with dilated right heart chambers or pulmonary arteries, thrombi can form at those sites and embolize distally into the branches of the pulmonary artery.

The likelihood of embolism is influenced by the location of thrombi in the veins of the lower extremity. Although the majority of thrombi originate in the veins of the calf, it has been clearly demonstrated that thrombi that remain limited to the calf veins rarely result in PE.⁵⁷ However, 15% to 25% of symptomatic, isolated calf thrombi when left untreated will extend to involve the proximal veins (popliteal, superficial femoral, and common femoral veins, or even more proximally).^{58,59} (It is worth emphasizing that the superficial femoral vein is actually not superficial and represents one of the deep veins.⁶⁰) Proximal extension poses a risk of embolization that approaches 50%.^{61,62} For that reason, about one in eight patients with distal deep vein thromboses will develop PE.⁵³

This natural history of DVT has several important diagnostic and therapeutic implications. First, because the vast majority of emboli arise from thrombi in the veins in the lower extremity, diagnostic approaches to DVT can focus on techniques that detect lower extremity DVT. Second, techniques that detect above-knee thrombi are of particular value whether or not they can detect calf-limited thrombi. Finally, although it is true that calf-limited thrombi rarely embolize, many have incorrectly concluded from this information that *symptomatic*, calf-limited DVT represents a clinically irrelevant condition. Calf-limited thrombi may extend proximally. Furthermore, symptomatic calf vein thrombosis appears to be subject to recurrence, albeit at a lower risk than proximal vein thrombosis.^{59,63}

Although most above-knee thrombi represent extensions from calf thrombi, some do arise in the larger, proximal veins *de novo*. This appears to be restricted principally to patients with hip fracture or replacement, pelvic surgery (including prostatic resection), and other high inguinal pelvic trauma.

At any time during this process, a portion or all of the thrombus can detach as an embolus. This risk is highest early in thrombus development before there is significant fibrinolysis or organization. Beyond this acute phase, the long-term outlook is influenced principally by the extent of residual venous obstruction and valvular damage. If significant obstruction or valvular damage persists, downstream stasis will be present, leading to a risk of recurrent DVT and development of the postphlebotic syndrome.^{64,65}

NATURAL HISTORY: PULMONARY EMBOLISM

PE causes a number of consequences to gas exchange and other pulmonary functions.⁶⁶ Regional obstruction to pulmonary blood flow and diversion of the flow to unobstructed portions of the lung may alter the ventilation-perfusion balance in both the obstructed and unobstructed regions.^{67,68} In the regions with pulmonary vascular obstruction, alveolar dead space is created.⁶⁹ If a region's blood flow is severely obstructed, there may be bronchoconstriction in the lung distal to the area of obstruction as a result of alveolar hypocapnia.⁷⁰ This is probably uncommon in patients because they are free to inhale carbon dioxide-rich dead-space air into the associated lung regions and because obstruction is rarely total. PE almost always leads to hyperventilation, the mechanism for which remains uncertain.

The characteristic gas exchange abnormality is hypoxemia, generally caused by the venous admixture due to areas of low ventilation/perfusion ratio or of shunt. Arterial hypoxemia may be worsened when acute increases in right ventricular afterload lower the cardiac output enough to widen the arteriovenous oxygen difference and decrease the oxygen saturation of mixed venous blood.⁷¹ This lowering of the mixed venous oxygen content magnifies the effects of the normal venous admixture, thereby further lowering the resultant arterial oxygen pressure (PO_2). Another potential mechanism for hypoxemia in patients with massive PE is right-to-left shunt, on either an intrapulmonary or intracardiac basis.⁷² With embolic occlusion sufficient to increase pulmonary artery pressure, hypoxic vasoconstrictive mechanisms can be overwhelmed and perfusion may increase in poorly ventilated or nonventilated lung regions. On occasion, embolic events massive enough to increase right atrial pressure may result in intracardiac right-to-left shunting through a patent foramen ovale. The final mechanism for hypoxemia relates to the loss of pulmonary surfactant.⁷³ Surfactant is not lost immediately; it requires approximately 24 hours of total occlusion and lack of blood flow to develop. At that time or later, surfactant becomes depleted in the obstructed alveolar zones, resulting in atelectasis and edema. If the thrombus resolves and perfusion to this atelectatic region resumes, hypoxemia may result.

One uncommon local consequence of PE is pulmonary infarction. Infarction is uncommon because the pulmonary parenchyma has three potential sources of oxygen: the pulmonary arteries, the bronchial arteries, and the conducting airways.⁷⁴ In patients with no coexisting cardiopulmonary disease, large infarctions (such as those visible by chest radiography) are rare.^{75,76} However, autopsy series suggest that infarctions of smaller pulmonary arteries are more common.^{77,78} Infarction develops in approximately 20% to 33% of patients with significant cardiac or pulmonary disease that compromises either bronchial arterial flow or airway patency. In patients with left ventricular failure, infarction may result if the increased pulmonary venous pressure compromises bronchial flow.⁷⁹

The cardiac and hemodynamic effects of embolism are related to three factors: the degree of reduction of the cross-sectional area of the pulmonary vascular bed, the preexisting status of the cardiopulmonary system, and the physiologic consequences of both hypoxic-mediated and neurohumorally mediated vasoconstriction.⁸⁰⁻⁸⁵ Mechanical obstruction of the pulmonary vascular bed by embolism accounts for most of the increase in *pulmonary vascular resistance* (PVR), although resistance is typically worsened by release of vasoconstrictive substances such as endothelin, thromboxane A₂, and serotonin.^{86,87} The combination of factors acutely increases the workload on the right ventricle, a chamber ill-equipped to deal with an acute elevation in pressure load. In patients without preexisting cardiopulmonary disease, obstruction of less than 20% of the pulmonary vascular bed results in a number of compensatory events that minimize adverse hemodynamic consequences. Pulmonary vessels are recruited and become distended, resulting in a normal or near-normal PVR and pulmonary artery pressure; cardiac output is maintained by increases in the right ventricular stroke volume and increases in the heart rate. As the degree of pulmonary vascular obstruction exceeds 30% to 40%, there are increases in pulmonary artery pressure and modest increases in right atrial pressure. The Frank-Starling mechanism maintains right ventricular stroke work and cardiac output. When the degree of pulmonary artery obstruction exceeds 50% to 60%, compensatory mechanisms are overwhelmed, cardiac output begins to fall, and right atrial pressure increases dramatically. With acute obstruction beyond this amount, the right heart dilates, right ventricular wall tension increases, right ventricular ischemia may develop, the cardiac output falls, and systemic hypotension develops. Hypotension worsens the situation by decreasing the coronary perfusion pressure to the already tense right ventricle.⁸⁸ In patients without prior cardiopulmonary disease, the maximal mean pulmonary artery pressure that can be generated by the right ventricle appears to be 40 mm Hg (representing a pulmonary artery systolic pressure of ≈ 70 mm Hg). The correlation between the extent of pulmonary vascular obstruction and PVR appears to be hyperbolic; with increasing vascular obstruction, PVR rises slowly as the remaining pulmonary vascular bed expands and recruits additional vessels and then rises rapidly when that reserve is exhausted.⁸⁹

The hemodynamic response to acute PE in patients with preexisting cardiopulmonary disease may be considerably different from that in patients without prior disease.⁸⁵ In

patients without prior cardiopulmonary disease, there is a general relationship between the rise in pulmonary artery pressure and the pulmonary vascular obstruction, whereas in patients with prior cardiopulmonary disease, pulmonary artery pressures may rise disproportionately. As a result, severe pulmonary hypertension may develop in response to a relatively small reduction in pulmonary artery cross-sectional area. In addition, evidence of right ventricular hypertrophy (rather than right ventricular dilation) associated with a mean pulmonary artery pressure in excess of 40 mm Hg (pulmonary artery systolic pressure in excess of ≈ 70 mm Hg) in a patient suspected of embolism should suggest an element of chronic pulmonary hypertension resulting from a potentially diverse group of etiologic possibilities (e.g., chronic thromboembolic pulmonary hypertension, left ventricular failure, valvular disease, right-to-left cardiac shunts).

Beyond the acute embolic event, the behavior of emboli parallels that previously described for venous thrombi; that is, they undergo resolution by fibrinolysis, by organization and recanalization, or both. Although there is a great deal of interpatient variability, resolution of PEs typically is substantial during the first week, somewhat more gradual for the next 4 to 8 weeks, and then slow thereafter.^{69,90-95} (The most rapid resolution of a large embolus that has been documented is 51 hours.⁹⁶) The term *resolution* is used here because it is uncertain, in humans, to what degree lysis (versus organization) participates in embolic resolution. Most sequential data regarding resolution in humans are based on perfusion scan, not angiographic, data. However, these data suggest that residual anatomic defects are common following embolism and, contrary to prior opinion, that complete restoration of pulmonary blood flow represents the exception rather than the rule.^{69,90-95} In terms of hemodynamic resolution, it would appear that a stable pulmonary artery pressure is reached within 6 weeks.⁹⁷ How often anatomic and mild hemodynamic residuals persist is not known. Nearly one third of patients with acute PE may have residual perfusion defects, which may be associated with a spectrum of symptoms including dyspnea, lower exercise tolerance, and higher pulmonary arterial pressures of various intensities.⁹⁸ However, residual obstruction sufficient to cause clinically significant pulmonary hypertension is rare. For this small group of patients with significant residual obstruction, the clinical course and management are dealt with later in this chapter.

CLINICAL PRESENTATION

The most common symptoms and physical findings of venous thrombosis include swelling, pain, erythema, and warmth. "Classic" findings such as *Homan sign* (calf pain with flexion of the knee and dorsiflexion of the ankle), *Moses sign* (pain with calf compression against the tibia), or a palpable cord are infrequent and nonspecific.

As established by multiple investigations, the clinical diagnosis of venous thrombosis is imprecise.^{52,99-102} In patients with clinical signs and symptoms suggestive of venous thrombosis, 60% to 80% will not have the diagnosis by objective testing. Furthermore, and even more disquieting, the majority of high-risk patients who are

monitored and who develop DVT will not have signs or symptoms suggesting the diagnosis.¹⁰³ Algorithmic clinical models incorporating risk factors, symptoms, and physical signs have been demonstrated to have the ability to stratify *symptomatic* patients into risk categories, although not to a level in which clinical diagnosis, in the absence of objective testing, can be relied on either to confirm or exclude the diagnosis.^{101,104} The differential diagnosis of DVT is extensive and includes cellulitis, arthritis, muscular injury or tear, neuropathy, arterial insufficiency, lymphedema, ruptured Baker cyst, superficial thrombophlebitis, and chronic venous insufficiency.

Similarly, the diagnosis of PE cannot be confirmed or excluded solely on clinical grounds.¹⁰⁵⁻¹⁰⁷ However, recognition of the clinical signs and symptoms associated with PE is valuable because clinical findings and clinical suspicion represent an essential first step in the diagnostic pathway. Although a somewhat arbitrary classification because presenting symptoms and signs of embolism frequently overlap, the presentation of PE can be categorized into one of three clinical syndromes: (1) isolated dyspnea; (2) pleuritic pain or hemoptysis; and (3) circulatory collapse.¹⁰⁸ Among patients without prior cardiopulmonary disease in the *Prospective Investigation of Pulmonary Embolism Diagnosis* (PIOPED) study, the syndrome of pleuritic pain or hemoptysis was the most common mode of presentation, seen in approximately 60% of patients; isolated dyspnea was noted in approximately 25%, and circulatory collapse in 10%.

The most common presenting symptom of acute embolism is the sudden onset of dyspnea.¹⁰⁷⁻¹⁰⁹ In various studies, dyspnea was a presenting symptom in the majority of patients. However, it must be emphasized that, in the PIOPED study,¹⁰⁹ dyspnea was not present in 27% of patients ultimately proven to have embolism. Pleuritic chest pain was present in 66% of patients, whereas hemoptysis (15%) was uncommon. Less than 50% of patients had cough (37%), leg swelling (28%), and leg pain (26%). A sense of impending doom also is reported, particularly with massive embolism. Angina also can result from massive embolism representing, in this circumstance, right ventricular ischemia. Syncope also may be a presenting complaint in major embolic occlusion.

The most common physical finding is tachypnea (respiratory rate >20/min). In the PIOPED study,¹⁰⁹ however, tachypnea was not present in approximately 30% of patients with embolism. Clinical findings noted less frequently include crackles (55%), tachycardia (30%), and an increased pulmonic component of the second heart sound (S2; 23%). Fever may develop some hours after the event and often reaches but rarely exceeds 38.3° C. As noted previously, hemoptysis may be observed; it usually is quite modest in extent, although it may persist for some days. Brisk hemoptysis is rare and is almost never the initial finding. With massive embolism, there may be evidence of right ventricular overload or failure, such as a right ventricular tap along the left sternal border and an accentuated pulmonary valve closure sound. If right ventricular failure develops, there may be narrowed or fixed splitting of an S2, an S3, and/or an S4, distended neck veins, and cyanosis. Careful examination of the legs may elicit evidence suggesting venous

thrombosis. In the PIOPED study,¹⁰⁹ clinically apparent venous thrombosis was found in only 15% of patients.

Obviously, these symptoms and signs are nonspecific. In the PIOPED study,^{108,109} none of the presenting symptoms was capable of discriminating between patients with positive and negative angiograms. Also, in terms of presenting signs, only the presence of crackles, an S4, and an increased pulmonic component of S2 could differentiate between those with positive and negative angiograms.^{108,109} Furthermore, in patients with underlying cardiopulmonary disease, the presenting symptoms and signs frequently may be obscured by elements of the underlying illness.¹⁰⁶ It is also important to recognize that the clinical presentation of embolism has been characterized in trials composed of *symptomatic* patients, although it is known that many PE do not produce symptoms. In prospective studies of high-risk patients with proximal DVT, PE can be documented in 40% of patients who had no symptoms of PE.^{61,105,110} It is likely that the frequency and severity of symptoms are influenced by the extent of embolic occlusion and the prior cardiopulmonary status of the patient. Small- or moderate-sized emboli may induce few or no symptoms in an otherwise normal individual. In patients with preexisting cardiopulmonary disease, symptoms are more common and severe.¹¹¹

Owing to the nonspecific presentation of PE, the differential diagnosis is varied and extensive, especially in hospitalized patients with coexisting cardiac or pulmonary disease. Common considerations include congestive heart failure, exacerbation of chronic lung disease, postoperative atelectasis, and viral pleurisy. PE presenting with fever, dyspnea, and chest radiographic abnormalities easily can be confused with a bacterial pneumonia. The presence of fever and leukocytosis (rarely >15,000 cells/μL) are uncommon but well-described accompaniments of VTE.^{112,113}

These precautionary statements regarding clinical diagnosis are not meant to suggest that the clinical presentation of venous thrombosis or PE cannot be used as a basis for clinical decision making. However, they are meant as a reminder that the clinical presentation of VTE and PE may often be atypical or subtle and should serve only to generate a suspicion of that diagnosis. A reliance on symptoms and signs that are considered “classic” before making the decision to proceed to confirmatory testing may lead to underdiagnosis and unnecessary mortality.

DIAGNOSIS OF VENOUS THROMBOSIS

The proper diagnostic approach to VTE must take into account the central fact that venous thrombosis and PE are manifestations of the same disease process: venous thrombosis representing the source of PE and PE representing a complication of venous thrombosis.

CONTRAST VENOGRAPHY

In validating any test, there must be a “gold standard.” In the case of lower extremity venous thrombosis, that

standard is contrast venography (Fig. 57-1). In investigative contexts, it is a good gold standard (as indicated later, however, that often is not the case in clinical contexts). The venogram is performed according to a specific protocol described by Rabinov and Paulin in 1972.¹¹⁴ The most reliable criterion for the diagnosis of venous thrombosis is a constant intraluminal filling defect evident in two or more

Figure 57-1 Venography for DVT. Contrast venogram shows a large filling defect (arrows) due to thrombus in the popliteal and distal superficial femoral veins. Such thrombi pose substantial embolic risk.

views. Other criteria such as nonvisualization of deep veins, presence of venous collaterals, or nonconstant filling defects are less reliable. Under circumstances in which the proper protocol and interpretative criteria are utilized, contrast venography has high sensitivity and specificity. However, the study is not without shortcomings. As those who have seen many venograms recognize, the study is not easy to interpret, especially in patients with a prior history of venous thrombosis. Venous cannulation may often be difficult, especially in the presence of edema; expert interpretation is essential for accurate diagnosis; injection of contrast material with its associated allergic and nephrotoxic risks is necessary; venous thrombosis may be induced by the procedure itself; and the cost, invasive nature, and discomfort of the study make sequential studies impractical.

Owing to these limitations, a number of noninvasive studies capable of being performed on a sequential basis were introduced into clinical practice. At present, duplex ultrasonography is the most commonly used noninvasive technique. *Magnetic resonance imaging* (MRI) and CT have proved capable of detecting thrombi, but their widespread utilization has been limited by cost, limited access, and, in the case of CT, the need for contrast administration.

DUPLEX ULTRASONOGRAPHY

Since the late 1990s, duplex ultrasonography, which refers to the combination of Doppler venous flow detection and real-time B-mode imaging, has assumed a central role in the noninvasive diagnosis of symptomatic lower extremity DVT.¹¹⁵ A number of criteria are used to diagnose venous thrombosis, the most reliable of which is the noncompressibility of a venous segment (Fig. 57-2). Secondary, less reliable criteria include the presence of echogenic material within the venous lumen (eFig. 57-1), venous distention, and loss of phasic change with respiration, lack of response at the *common femoral vein* (CFV) to Valsalva maneuver,

Figure 57-2 Compression ultrasonography for DVT. A, Rest and B, compression duplex ultrasonography demonstrates a noncompressible distal superficial femoral vein containing an echogenic mass (arrows), consistent with venous thrombosis.

diminished or absent color flow with color Doppler sonography (eFig. 57-2), and lack of augmentation of flow at the CFV with compression of the calf. The two signs showing a lack of increase in flow, either with Valsalva or with calf compression, can indicate obstruction of veins between the site of increased pressure and the measured vein. The absence of an echogenic luminal mass cannot be considered useful in excluding the diagnosis of venous thrombosis because acute thrombus may not demonstrate echogenicity (eFig. 57-3).

Multiple studies since the late 1990s have demonstrated sensitivities and specificities exceeding 95% in *symptomatic* patients with proximal venous thrombosis. Although simplified compression examinations limited to the symptomatic leg or to the common femoral and popliteal veins (rather than the entire lower extremity venous system) have been suggested, the time saved with such approaches is limited, and a number of isolated superficial femoral vein or calf-limited thrombi may be overlooked.¹¹⁶⁻¹¹⁸ Asymptomatic thrombi in the contralateral leg can be detected in approximately 5% to 10% of patients presenting with symptomatic acute venous thrombosis.¹¹⁹ Although the detection of asymptomatic, contralateral thrombi has little impact on the immediate management of the patient, it may have long-term consequences when recurrence is suspected. A more prudent approach appears to be a complete examination extending from the inguinal ligament to the popliteal vein and examination of the contralateral extremity if thrombus is detected in the symptomatic leg.

Duplex ultrasonography is less accurate in the detection of symptomatic calf-limited thrombi (sensitivity \approx 70%) and in asymptomatic proximal vein thrombi (sensitivity \approx 50%), thereby limiting its utility as a screening study in high-risk populations.¹²⁰ When ultrasonography is negative in patients with suspected venous thrombosis, a strategy of *serial* testing, consisting of one or two additional tests over the subsequent week, has proved to be effective in detecting proximal extension.¹²¹

MAGNETIC RESONANCE IMAGING

MRI techniques for detecting venous thrombosis include spin-echo magnetic resonance, gradient-recalled-echo magnetic resonance, and magnetic resonance venography. Preliminary reports suggest that MRI is at least as sensitive and specific as duplex ultrasonography.^{122,123} A potential advantage of MRI is that the entire length of the venous system, including the pelvic veins, can be evaluated. Disadvantages associated with MRI include cost and limited access, as well as the expertise required to perform and interpret the studies properly.

COMPUTED TOMOGRAPHY

The role of CT as a stand-alone test for venous thrombosis is limited. The sensitivity and specificity of CT venography are comparable with those of ultrasonography but mandate contrast injection with its associated risks and radiation exposure. Potential advantages of CT venography include the ability to visualize the pelvic veins (eFig. 57-4) and vena cava (eFig. 57-5). A diagnostic approach combining CT venography with *CT pulmonary angiography* (CTPA) may

have a role in patients undergoing evaluation for PE (see later).^{124,125}

HEMOSTASEOLOGIC ASSAYS

The development of a rapid and accurate blood test capable of diagnosing VTE has held special appeal and has been the subject of considerable investigative interest. A number of different serologic markers have been investigated, including D-dimer, fibrin monomer, prothrombin fragment, thrombin–antithrombin III complex, fibrinopeptide B, and fibronectin. Of these, D-dimer, alone and in combination with other noninvasive studies, has been subjected to the most rigorous clinical evaluation.^{126,127} D-dimer testing has proved to be highly sensitive but not specific; that is, elevated levels are present in nearly all patients with thromboembolism but also in a wide range of circumstances, including advancing age, pregnancy, trauma, infections, the postoperative period, inflammatory states, and malignancy. Therefore the role of D-dimer testing is limited to one of exclusion of VTE. Multiple assays have been developed with sensitivities that range from 80% to almost 100%.¹²⁶⁻¹²⁸ Highly sensitive assays, such as the enzyme-linked immunosorbent assay, are capable of excluding thromboembolism but are associated with such a high frequency of false-positive results that their clinical utility is limited.

Less sensitive assays (e.g., latex agglutination, red cell agglutination) lack the ability to exclude thromboembolism in isolation but have been used successfully in combination with either a clinical probability estimate or a noninvasive diagnostic study. Although potentially of substantial value in diagnostic pathways, the burgeoning selection of available assays, variations in sensitivity and specificity related to the type of assay, a range of discriminate values for positivity, and lack of standardization have limited generalized application of the technique due to uncertainty among clinicians regarding the predictive value of the particular test they are using. D-dimer testing has been used successfully as part of a number of different diagnostic strategies, and negative results of standardized, highly sensitive assays have proved capable of safely excluding venous thrombosis in outpatients presenting with a low or intermediate clinical likelihood of the disease.^{129,130}

CLINICAL PREDICTION RULES

A major advance in the diagnostic approach to both venous thrombosis and PE has been a transition from a technique-oriented approach to one that utilizes Bayesian analysis. In this strategy, the pretest probability of the disease, calculated independently of a particular test result either through empirical means or through a standardized prediction rule, is evaluated in combination with a test's likelihood ratio (derived from the sensitivity and specificity of that test) to create a posttest probability of the disease. This posttest probability can then be utilized as a basis for clinical judgment, either excluding the disease with a certain level of probability, confirming the disease with a certain level of probability, or supporting the need for additional diagnostic testing. This approach to diagnosis has proved especially useful in an era of noninvasive testing in which results are

often presented as probabilities rather than as discrete answers.

Several clinical prediction rules for venous thrombosis have been developed and validated.¹³¹ The Wells rule, initially described in 1995 and revised subsequently to include nine clinical features, proved capable of stratifying patients with suspected venous thrombosis into three probability categories—low, moderate, and high—in which the incidence of venous thrombosis approximates 3%, 17%, and 75%, respectively.¹³² By utilizing this prediction rule in combination with lower extremity ultrasonography, the diagnosis of venous thrombosis can be safely excluded in patients with a low clinical likelihood of venous thrombosis in combination with a negative lower extremity ultrasound and confirmed in patients with a high clinical probability and a positive lower extremity ultrasound. Such an approach dramatically reduces the need for contrast venography or serial lower extremity ultrasound studies.

The Wells prediction rule was again revised to include 10 clinical characteristics capable of stratifying outpatients into “clinically likely” and “clinically unlikely” categories (Table 57-2). For outpatients falling into the clinically unlikely category, DVT was reliably excluded when the result of a sensitive D-dimer assay was negative, thereby limiting the need for ultrasound evaluation.¹³⁰ The ability to exclude venous thrombosis in outpatients using a clinical prediction rule and negative results of a D-dimer assay has been confirmed in other studies.¹³³ It should be emphasized that clinical prediction rules constructed and validated in outpatients should be viewed critically before they are applied to an inpatient population.

Table 57-2 Wells Clinical Model for Predicting the Pretest Probability of Deep Venous Thrombosis

Clinical Characteristic	Score
Active cancer (patient receiving treatment for cancer within the previous 6 mo or currently receiving palliative treatment)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bedridden for 3 days or more, or major surgery within the previous 12 wk requiring general or regional anesthesia	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than that on the asymptomatic side (measured 10 cm below the tibial tuberosity)	1
Pitting edema confined to the symptomatic leg	1
Collateral superficial veins (nonvaricose)	1
Previously documented deep venous thrombosis	1
Alternate diagnosis at least as likely as deep venous thrombosis	-2
Score	Clinical Assessment Probability
<2 points	Unlikely
≥2 points	Likely

DIAGNOSIS OF PULMONARY EMBOLISM

Certain parallels between the approaches to the diagnosis of DVT and PE exist. Perhaps the most important parallels are that clinical evidence in isolation, although capable of raising the suspicion of the disease, cannot be relied on to confirm or exclude the diagnosis and that the use of clinical prediction rules in combination with noninvasive testing can substantially decrease the need for invasive diagnostic testing.

STANDARD LABORATORY EVALUATION

Routine laboratory studies cannot make the diagnosis of PE. Although none have the discriminatory power to confirm the diagnosis of embolism, they do provide valuable adjunctive information and support for therapeutic interventions and may confirm the presence of an alternative diagnosis.

The majority of patients with PE have abnormal chest radiographs.¹³⁴ However, these abnormalities are usually subtle, nonspecific, and therefore nondiagnostic (Fig. 57-3). In the PIOPED study,¹⁰⁹ the most common radiographic abnormalities were atelectasis and pulmonary opacities. There is some confusion about the diagnostic configuration of radiographic abnormalities due to embolism. Although usually abutting a pleural surface, the opacities can be of any shape, not necessarily wedge-shaped (eFig. 57-6). Although pleural effusions are seen in almost half of the patients, the majority of effusions are small and involve only blunting of the costophrenic angle.¹⁰⁷ Findings once considered specific for embolism, such as the *Westermarck sign* (focal areas of avascularity, eFig. 57-7), the *Hampton hump* (pleural-based, wedge-shaped opacity, eFig. 57-8), and the *Fleischner sign* (prominence of the central pulmonary artery, eFig. 57-9), have not proved to have discriminatory value. In a patient with hypoxemia or pulmonary complaints, a normal chest radiograph may be quite useful in raising the index of suspicion of embolism and in excluding confounding diagnostic options. The major roles of chest radiography in suspected PE, therefore, are to exclude competing diagnoses and, if ventilation-perfusion (V/Q) scanning is anticipated, to evaluate the pulmonary parenchyma.

Likewise, electrocardiographic findings in PE, although common, are diverse and nonspecific.¹³⁵ The most common abnormalities include nonspecific tachycardia, T wave inversion, and abnormalities of the ST segment. With more extensive occlusion, the electrocardiogram may reveal the more “classic” findings of right heart strain, including an “S₁Q₃T₃” pattern, a pseudoinfarction pattern (Qr in V₁), a complete or incomplete right bundle-branch block, or right axis deviation.^{135,136} Rhythm disturbances other than sinus tachycardia are uncommon and usually confined to patients with underlying cardiac disease.¹³⁵

Arterial blood gas analysis is helpful, although not definitive.¹³⁷ Arterial hypoxemia may be present, and the more massive the obstruction, the more severe the hypoxemia is likely to be. However, many other conditions also cause hypoxemia, and embolism often does not cause hypoxemia

Figure 57-3 Chest radiographs in a patient with pulmonary embolism. **A**, Opacities caused by atelectasis with edema in the right lower lobe and in the retrocardiac area in a patient with angiographically confirmed pulmonary embolus. **B**, Two weeks later, the opacities have cleared. (Courtesy Michael Gotway, MD.)

or even a widening of the alveolar-arterial PO_2 difference. Hypocapnia usually is present with embolism; hypercapnia, conversely, is rare. Hypercapnia appears with embolism only in patients with marked antecedent ventilatory limitation or when such limitation has been imposed because the patient is on controlled mechanical ventilation.

ECHOCARDIOGRAPHY

Echocardiography may serve a valuable role in the diagnostic approach to PE. Under appropriate clinical circumstances, the detection of unexplained right ventricular volume (eFig. 57-10A) or pressure overload might suggest the possibility of embolism and lead to confirmatory testing (eFig. 57-10B). A distinct echocardiographic pattern involving akinesia of the mid-free right ventricular wall with apical sparing has been described, known as McConnell sign (Video 57-1)^{138,139} Direct visualization of right heart chamber emboli is uncommon but possible (Video 57-2). Properly performed *transesophageal* echocardiography has demonstrated excellent specificity for the detection of proximal emboli that involve the pulmonary trunk and the right and left main pulmonary arteries.¹⁴⁰ Transesophageal echocardiography also has proved valuable in the evaluation of competing diagnostic possibilities such as right ventricular infarction, endocarditis, pericardial tamponade, and aortic dissection in patients with unexplained shock and evidence of elevated central venous pressure. The overall sensitivity of *transthoracic* echocardiography in PE approximates 50%.¹⁴¹ Therefore it cannot be considered a primary diagnostic technique. Consideration can be given to its use in that subset of patients with suspected massive PE who are too ill for transportation or who have an absolute contraindication to the administration of a contrast agent.

VENTILATION-PERFUSION SCANNING

Despite significant limitations, V/Q lung scanning can be a valuable step in the diagnosis of PE if one of the two definitive results are found (i.e., either a *negative* or a *high-probability* scan).^{109,142}

First, a negative study excludes the diagnosis of PE with the same degree of certainty as a negative pulmonary angiogram (Fig. 57-4) and with a higher degree of certainty than is achieved by a negative CT scan.¹⁴³ This conclusion is illustrated by the results of two large prospective clinical trials comparing perfusion scanning to pulmonary angiography, the PIOPED trial¹⁰⁹ (performed in the United States) and the *Prospective Investigative Study of Acute Pulmonary Embolism Diagnosis* (PISA-PED) trial¹⁴⁴ (performed in Europe). In both trials, normal pulmonary perfusion scanning was a highly sensitive method for excluding the presence of PE. The value of a normal perfusion scan was not diminished even in a subset of patients who had a high pretest probability for PE¹⁰⁹ or were critically ill.¹⁴⁵

The significance of a normal perfusion scan, as reported by the PIOPED and PISA-PED trials, is consistent with all published longitudinal studies.¹⁴⁶⁻¹⁴⁸ A meta-analysis of diagnostic studies for PE calculated the incidence of PE following a normal perfusion scan to be 0.3%.¹⁴⁹ A subsequent case series of consecutive patients followed clinically after objective testing for PE disclosed no PE in 188 patients who had normal perfusion scans.¹⁵⁰ These data support the clinical guidelines of the American Thoracic Society,¹⁵¹ British Thoracic Society,¹⁵² American Heart Association,¹⁵³ and European Society of Cardiology,¹⁵⁴ all of which recommend that a normal perfusion scan be accepted as reliably ruling out PE, with the same validity as a pulmonary angiogram.

Second, a “high-probability” study (one characterized by multiple, segmental-sized, mismatched defects) is associated with embolism in approximately 87% of patients, as shown in the PIOPED study¹⁰⁹; when coupled with a high clinical probability of embolism, the positive predictive value increased to 96% (Fig. 57-5).

Limitations of V/Q scanning are significant. For example, the PIOPED data provided several pieces of disquieting information: (1) the overwhelming majority of patients with suspected embolism did not have scan findings that fell into a high-probability or normal category, the only categories that can be considered definitive; (2) the majority of patients with embolism did not have a high-probability scan finding; (3) the overwhelming majority of patients without

Figure 57-4 Normal six-view lung perfusion scan. This finding is capable of excluding the diagnosis of embolism.

Figure 57-5 Lung perfusion (Q) scan shows major segmental and lobar defects bilaterally. The ventilation scan (not shown) and chest radiograph were normal. This pattern is strongly associated with the presence of embolism.

embolism did not have a normal scan; and (4) a substantial and clinically significant percentage of patients with scan findings interpreted as intermediate probability (33%) and low probability (16%) were subsequently demonstrated to have angiographic evidence of embolism.¹⁰⁹ It is essential that clinicians recognize that the concept of a low-probability scan (eFig. 57-11) is misleading and potentially dangerous because of the frequency of PE in patients exhibiting this scan pattern.¹⁵⁵

In order to improve perfusion scan specificity, traditional interpretive criteria, including the PIOPED criteria, rely on the number and size of the perfusion defects, as well as on the results of a concurrent ventilation image. The intended basis for doing so is to differentiate primary *vascular* obstruction (“mismatched” defects) from primary *parenchymal* disorders that result in compensatory pulmonary vasoconstriction (“matched” defects). The PISA-PED investigators¹⁵⁶ utilized a fundamentally different interpretive scheme that relied on the shape of the perfusion defects regardless of their number or size or their association with ventilation findings. The results of this study suggest that embolism can be diagnosed accurately and the need for angiography limited by perfusion results combined with an assessment of clinical likelihood in the absence of ventilation imaging. An analysis of a subset of patients from the PIOPED study came to a similar conclusion.¹⁵⁷

The diagnostic approach to PE in patients with underlying *chronic obstructive pulmonary disease* (COPD) remains especially problematic because the presentation of PE in this population may closely mimic an exacerbation of their underlying disease. Unfortunately, the value of V/Q scanning in this population is even more limited than that in the general population because an even higher proportion of scans fall into an indeterminate category.¹⁵⁸ However, among the more than half of COPD patients who had high-probability, normal, or near-normal scans, both the positive predictive value and the negative predictive value were equivalent to that in the general population.

COMPUTED TOMOGRAPHY PULMONARY ANGIOGRAPHY

CTPA has represented a major advance in the diagnosis of PE (see also Chapter 18). Unlike V/Q scanning, it provides

Figure 57-6 CT pulmonary angiography of pulmonary embolism. A–D, Chest CT pulmonary angiography shows bilateral pulmonary emboli, including a “saddle” embolism (black arrowheads, **B** and **C**); right upper lobe emboli (white arrowheads, **A** and **C**), and interlobar emboli (arrows, **B–D**). For a video clip of the full CT study, see [Video 57-3](#).

the ability to visualize emboli directly, as well as to detect parenchymal abnormalities that may support the diagnosis of embolism or provide an alternative basis for the patient's complaints ([Fig. 57-6](#); [Video 57-3](#)). The reported sensitivity of chest CT scanning for embolism has ranged from 57% to 100%, with a specificity ranging from 78% to 100%.¹⁵⁹ Factors responsible for this wide divergence relate to the proximal extent of vascular obstruction that can be detected and, in part, to advances in CT technology that allow higher resolution, dramatically faster scanning times, more peripheral visualization, and less motion artifact than that provided by earlier-generation scanners. Sensitivity and specificity of CT scanning for emboli involving the main and lobar pulmonary arteries exceeds 95%. Vascular involvement confined to segmental or subsegmental pulmonary vessels is associated with a decline in both sensitivity and specificity. In one series, the sensitivity of CT scanning for subsegmental arteries reported by two readers ranged between 71% and 84% even after nonevaluable scans were excluded.¹⁶⁰ Isolated involvement of the subsegmental pulmonary arteries is not unusual and, in various series, may be found in up to 30% of patients.^{161,162} These findings suggest that filling defects consistent with embolism involving the main or lobar pulmonary arteries can be considered diagnostic of embolism. By contrast, defects involving the segmental and subsegmental arteries can be considered suggestive of embolism but should be supported by additional objective data. The absence of detectable filling

defects reduces the likelihood of embolism but appears incapable of excluding the possibility with the same degree of certainty as a negative V/Q scan. The importance of treating patients with CTPA findings suggestive of *exclusively* subsegmental emboli has been questioned recently, especially in patients with good cardiopulmonary reserve and no coexisting DVT or persistent risk factors. However, no large trials have yet demonstrated the safety of withholding anticoagulants in this patient population.¹⁶³

Although CTPA scanning has increased the number of cases of acute PE that are diagnosed,¹⁶⁴ it has inherent limitations. The technique requires infusion of intravascular iodinated contrast agents, and the most common serious complications of testing arise from their use. During CT scanning, the peripherally infused dye fills the lumen of the pulmonary arteries, hopefully at the exact time that the chest is imaged. Emboli are detected as focal defects in pulmonary artery filling. When performed and interpreted expertly, CTPA scans are capable of identifying emboli in the segmental or larger pulmonary arteries (as does V/Q scanning^{165,166}). However, certain areas, such as the hila, are prone to false positives. Reading emboli in these areas should be done with special care. Perhaps more importantly, CT scans have difficulty imaging emboli in subsegmental pulmonary arteries. In selected populations, smaller emboli may account for up to 20% to 30% of PEs^{161,167} and represent the very cases in which V/Q scans are the most limited.¹⁰⁹

The National Institutes of Health-funded *Prospective Investigation of Pulmonary Embolism Diagnosis-2* (PIOPED-2) study highlighted the strengths and limitations of CTPA.¹²⁵ Before enrolling the study population of 1090 patients, the investigators excluded 1350 patients because their abnormal creatinine levels reflected some degree of renal dysfunction, which would have increased the risk involved with the administration of contrast dye. An additional 272 patients were excluded because of a history of contrast dye allergy. During the performance of the trial, 6% of the scans were excluded because the images were of poor quality. Even after the inconclusive scans were disregarded, the sensitivity of the chest CT scans was only 83%, although it is difficult to be confident of the gold standard used to compare to CTPA.

The PIOPED-2 investigators also excluded another 976 patients from the study because they had histories of long-term anticoagulation therapy. This highlights another weakness of CTPA in that luminal filling defects remain long after an acute pulmonary embolic event, so the test cannot easily differentiate between chronic and acute VTE. This is clinically relevant because the rate of recurrence is about 7% during the half-year after an acute PE and about 3% per year for the subsequent 5 years.¹⁶⁸

Finally, CTPA can expose patients to clinically significant doses of radiation.^{169,170} Current clinical protocols deliver a radiation dose to the female breast ranging from 4 to 6 cGy per scan.¹⁷⁰ This dose is especially concerning because most CTPA evaluations are negative, even when the criteria for scanning are rigorously followed.^{125,142} In addition, because PE has a relatively high rate of recurrence, patients are commonly reimaged after their first embolism. Younger women, who have a known elevated incidence of PE, are particularly at risk from radiation damage to breast and lungs.

From a clinical (outcomes-based) perspective, CT scanning and V/Q scanning have many similarities, and either can be used to exclude clinically significant PE in stable patients under many circumstances. Outcome studies have demonstrated that withholding anticoagulant therapy in patients with a negative CT scan coupled with a negative lower extremity ultrasound study appears to be a safe strategy except in those patients who present with a high clinical likelihood of embolism.^{171,172} Similarly, withholding anticoagulation from patients with “non-high-probability” findings on V/Q scan coupled with negative lower extremity studies is safe, except in those with inadequate cardiopulmonary reserve.^{173,174} A recent randomized, controlled trial comparing CT and V/Q for the management of suspected PE found the two studies to be comparable for excluding clinically significant PE.¹⁴² Specifically, the study disclosed no difference in outcome among patients in whom anticoagulation was withheld on the basis of the combination of a negative CT and negative leg studies compared with patients in whom anticoagulation was withheld based on the combination of a “non-high-probability” V/Q scan and negative leg studies or on a negative V/Q scan (without the need for leg studies). However, it should be emphasized that the outcome studies were done on relatively stable patients. Those with instability or poor cardiopulmonary reserve may require a higher degree of diagnostic certainty in order to rule out PE.¹⁷⁴

SINGLE-PHOTON EMISSION COMPUTED TOMOGRAPHY VENTILATION/PERFUSION SCANS

Single-photon emission computed tomography (SPECT) is a nuclear medicine technique that constructs three-dimensional images from scintigraphic data, in a similar way that CT constructs three-dimensional images from transmitted radiographs. SPECT ventilation and perfusion imaging (SPECT-V/Q) is a promising tool for diagnosing acute PE.¹⁷⁵⁻¹⁷⁷ The tomographic images can identify perfusion defects in areas of the lung that are hard to visualize with planar V/Q scans because of interposing lung tissue (e.g., the medial basilar segments of the lower lobes¹⁷⁸). As a result, SPECT-V/Q has far fewer nondiagnostic test results than planar V/Q, which removes one of the major limitations of planar V/Q testing. In fact, nondiagnostic results were reported in only 0.5% to 3% of SPECT-V/Q studies.¹⁷⁹⁻¹⁸¹ Another advantage of SPECT-V/Q is that it delivers only about one fourth of the radiation to the breast tissue than what is typical for CTPA scans.¹⁸²

Although the lack of a diagnostic gold standard limits our knowledge of its true accuracy (a phenomenon common to many tests for PE), several different analyses support the accuracy of SPECT-V/Q for PE. SPECT-V/Q had a high degree of agreement with the results of CTPA in patients suspected of having PE.¹⁸⁰ When compared with consensus diagnoses of PE (which, admittedly, included the SPECT-V/Q results themselves) SPECT-V/Q had sensitivities and specificities for PE that were typically in the 95% to 100% range.^{180,183,184} Similar to studies with CTPA scans, the clinical outcomes of patients with negative SPECT-V/Q, in whom anticoagulation was not given, were excellent.^{179,181,185} These findings suggest that SPECT-V/Q is highly sensitive for clinically important PE in the populations tested.

SPECT-V/Q is a promising technique but has not undergone extensive testing sufficient to merit replacement of CTPA as the primary diagnostic tool for PE. It may be especially useful for patients with nondiagnostic CTPA results or in those in whom the lower radiation dose to the chest would be especially advantageous. It may be useful as well for the follow-up of PE patients in order to detect and quantify residual perfusion defects.

LOWER EXTREMITY VENOUS EVALUATION

Because the majority of PEs arise from the deep veins of the lower extremities, the detection of lower extremity proximal vein thrombosis in a patient suspected of embolism, although not confirming PE, is strongly suggestive of that diagnosis and has an equivalent therapeutic implication. Positive ultrasound findings without symptoms or signs referable to the lower extremities should be interpreted judiciously, especially in patients with low pretest probability of PE, because even a highly specific test can yield false-positive results in some circumstances.¹⁸⁶ Lower extremity ultrasonography has a low yield in patients without leg symptoms or risk factors strongly suggestive of thromboembolism.^{187,188} Conversely, it is typically positive in only about 10% to 20% of patients with suspected PE and in 50% of patients with proven PE.¹⁸⁹ Therefore a negative ultrasound

finding cannot exclude the diagnosis. CT venography (see eFig. 57-4) as an adjunct to chest CTPA scanning appears to be capable of detecting femoropopliteal thrombosis with the same accuracy as duplex ultrasonography while also detecting pelvic and abdominal thrombosis.^{124,125} However, the combined CT technique is technically complicated¹²⁵ and significantly increases the amount of pelvic radiation exposure to the patient.^{169,170,190}

D-DIMER TESTING

The utility of D-dimer testing in PE diagnostic pathways is limited by the same shortfalls as those encountered in venous thrombosis pathways (i.e., a low specificity, which makes it most useful as an exclusionary technique in outpatients, and a lack of standardization). However, studies have demonstrated that a normal D-dimer result can safely exclude embolism in patients with a low clinical probability of disease.¹⁹¹⁻¹⁹³ Although preliminary data suggest that a highly sensitive assay is capable of excluding embolism at all levels of clinical probability, these results require confirmation.¹⁹³

PULMONARY ANGIOGRAPHY

The studies reviewed to date are capable of excluding or confirming the diagnosis of embolism in the majority of patients with suspected embolism. Angiography should be considered in patients in whom the diagnosis has not been confirmed or excluded using noninvasive techniques and when it is considered unsafe to withhold anticoagulation, when cardiopulmonary instability is present, and when the results of diagnostic testing are at such odds with the clinical impression as to warrant the risk of the procedure. Like contrast venography, however, pulmonary angiography has a number of limitations as a gold standard. First, the procedure is invasive and not without risk, especially in patients with acute right ventricular failure. However, experience has demonstrated that the perception of risk associated with angiography outweighs the actual risk.^{194,195} Pulmonary angiography can be performed quite safely if certain safeguards are observed and experienced personnel are involved.

Even though the risk of angiography should be nominal, the procedure has other limitations. One is accessibility: Angiography is performed in a special facility to which the patient must be transported. In some institutions, the logistical problems involved are modest; in others, they are substantial. The other limitation is interpretation. The interpretation of pulmonary angiograms is heavily influenced by three factors: location of the thromboembolic obstruction, quality of the images, and experience of the interpreters. Only two angiographic findings are diagnostic of acute embolism: the filling defect and abrupt cutoff of a vessel (Fig. 57-7). Technical adequacy of the angiogram is critical to accurate identification of both. Flow artifacts can falsely suggest a filling defect. It is essential that good vessel opacification be obtained and that the filling defects be identified as present on a sequence of images.

Although concern about risk should not deter pulmonary angiography, there are noteworthy limitations on its performance and value. Still, it is a rather odd commentary

Figure 57-7 Pulmonary angiography for pulmonary embolism. Left-sided pulmonary angiogram shows extensive filling defects within the left pulmonary artery (arrow) and the upper lobe, lingula, and lower lobe arteries, consistent with the diagnosis of pulmonary embolism.

on medical thinking that few would advise against performance of a coronary angiogram in a patient with coronary thrombosis or ischemia because of risk, yet the question of risk often deters pulmonary angiography in a patient in whom embolism is suspected. Given that the case-fatality rate of undiagnosed and untreated embolism exceeds that of myocardial infarction, it is not clear why this disparity exists; it should not exist, given equal competence in the performance and interpretation of these two procedures.

CLINICAL PREDICTION RULES

The development of clinical prediction rules has aided the diagnostic approach to PE, as it has the diagnostic approach to venous thrombosis. A number of standardized prediction rules that range widely in their complexity have been evaluated and published. Simple, standardized prediction rules (Table 57-3) involve information that can be easily acquired even in an outpatient setting or the emergency department.^{191,196} Complicated prediction rules involve an increased number of clinical variables and require expert interpretation of radiographic and electrocardiographic data.^{197,198} Alternatively, the clinician may make a subjective (“gestalt”) assessment of the probability of PE. So long as it is performed deliberately and independently of subsequent testing, the “gestalt” method appears to have comparable sensitivity to clinical prediction rules.¹⁹⁹

Although probability assessments, whether empirical or standardized, are incapable of confirming or excluding the presence of PE with a clinically acceptable degree of certainty, they have proved capable of stratifying patients into categories of likelihood. By combining this derived clinical probability with the results of a noninvasive diagnostic technique, diagnostic accuracy in terms of both the confirmation and the exclusion of embolism can be increased well

Table 57-3 Wells Clinical Model for Predicting the Pretest Probability of Pulmonary Embolism

Variable	Points Assigned
Clinical signs and symptoms of deep venous thrombosis	3.0
An alternative diagnosis is less likely than pulmonary embolism	3.0
Heart rate >100 beats/min	1.5
Immobilization or surgery in the previous 4 wk	1.5
Previous deep venous thrombosis or pulmonary embolism	1.5
Hemoptysis	1.0
Malignancy (on treatment, treated in the past 6 mo, or palliative)	1.0
Score	Clinical Assessment Probability
<2 points	Low probability
2–6 points	Intermediate probability
>6 points	High probability

From Kearon C: Diagnosis of pulmonary embolism. *CMAJ* 168:183–194, 2003.

beyond that achieved by the use of either clinical probability or the noninvasive diagnostic technique alone. In addition, the appropriate application of clinical prediction rules and D-dimer testing can substantially limit the number of patients who require thoracic imaging.²⁰⁰⁻²⁰²

In summary, an almost bewildering array of diagnostic techniques is available for patients with suspected VTE. What the clinician at the bedside must understand and accept is that multiple approaches are possible and that a stepwise diagnostic strategy, rather than any single diagnostic technique, may be necessary to confirm or exclude the diagnosis (Fig. 57-8). Furthermore, the clinician must understand that these steps are essential and potentially lifesaving. Withholding anticoagulation in a patient who has suffered an embolic event places that patient at risk for recurrent, potentially lethal events; instituting empirical anticoagulant therapy in a patient who has not suffered an embolic event involves unnecessary hospitalization and therapy, places the patient at risk for hemorrhagic complications, and establishes a “preexisting” condition that may adversely affect future health care costs. Finally, the clinician must understand that the use of a clinical prediction rule derived from an outpatient population might have a very different predictive value when applied to a less healthy inpatient population.

Many strategies to confirm or exclude the diagnosis of PE have been investigated. Because the initiating point for the diagnostic pathway begins with clinical suspicion, the following discussion centers about that approach. Also, given substantial variations in practice that currently exist, strategies that incorporate V/Q scanning or CTPA as the initial objective diagnostic technique are considered.

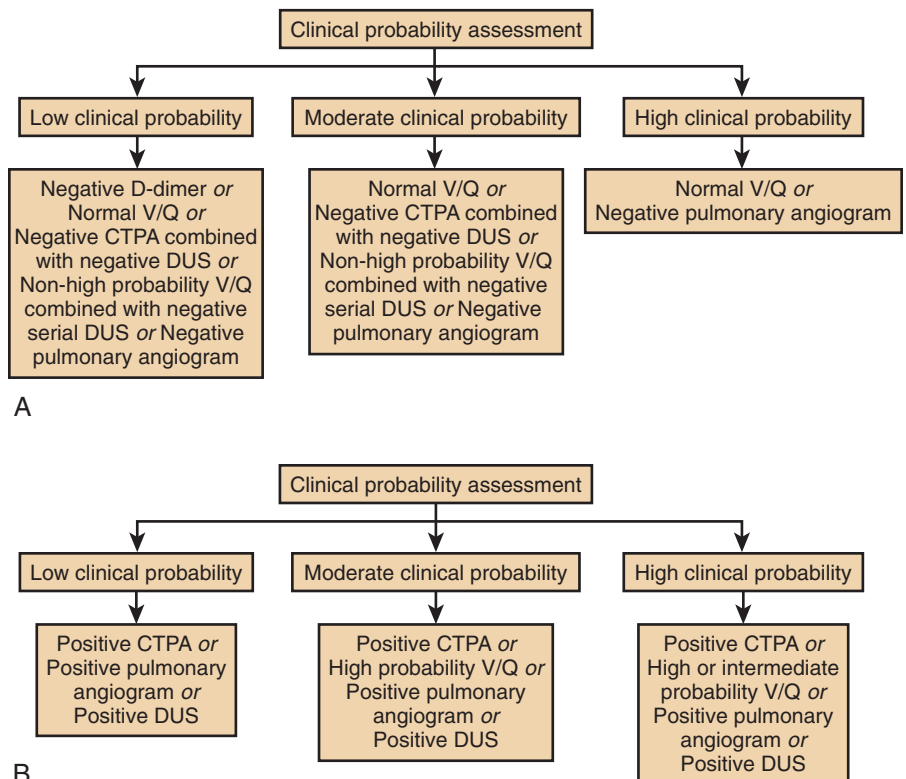

Figure 57-8 Diagnostic strategies capable of excluding (A) and confirming (B) the diagnosis of pulmonary embolism. CTPA, computed tomographic pulmonary angiography; DUS, Doppler ultrasound; serial DUS, serial Doppler ultrasound (1–2 additional tests over the subsequent week); V/Q, ventilation-perfusion scan.

In patients in whom the clinical suspicion of PE is considered high (>70% likelihood), a positive CTPA scan or a high-probability V/Q scan or SPECT-V/Q scan result would be considered diagnostic of embolism with greater than 95% certainty, whereas a negative perfusion scan (planar or SPECT) would exclude the diagnosis. In all other patients (non-high-probability planar V/Q scan or SPECT-V/Q or negative CTPA scan), lower extremity evaluation may be undertaken. A positive study would confirm the diagnosis. In the remaining patients, several strategies are possible. Serial lower extremity evaluations could be performed. Although not excluding embolism, negative results would suggest that the likelihood of recurrence is small. Alternatively, pulmonary angiography could be performed. This latter approach is especially applicable to unstable patients with preexisting cardiopulmonary disease, in whom the consequences of recurrence could be catastrophic.

When the clinical assessment is taken into account, the predictive value of CTPA varies substantially, especially when there is discordance between the clinical assessment and the CT finding. Both the positive predictive value of CTPA in patients with a low clinical probability and the negative predictive value in those with a high clinical probability are in the range of 60%. In patients with a low clinical probability of disease, a negative, highly sensitive D-dimer assay; a negative CTPA; or a normal V/Q scan are capable of excluding the disease. In those same patients, confirmation of the disease can be accomplished with a lower extremity duplex ultrasonography showing proximal DVT or by conventional pulmonary angiography. A high or intermediate probability V/Q scan or a positive CTPA, especially when the involved areas of embolism are beyond the segmental level, should raise questions about the diagnosis and lead to additional diagnostic testing.

Special circumstances that may guide the diagnostic approach do exist. In the setting of severe, preexisting pulmonary parenchymal or airway disease, planar V/Q scanning is of limited utility given the high likelihood that the scan result will be nondiagnostic. Although the positive predictive value of a high-probability scan and the negative predictive value of a normal or near-normal scan in patients with underlying lung disease are similar to that in the general population, the proportion of patients whose scans fall into a nondiagnostic category is increased substantially.¹⁵⁸ Under this circumstance, an approach utilizing chest CTPA scanning or SPECT-V/Q as the initial objective diagnostic study would be appropriate. The use of iodinated contrast required for CT scanning has been reduced over the years but nonetheless poses some risk of radiocontrast-induced nephropathy for patients with preexisting renal insufficiency, especially when it is associated with diabetes mellitus.²⁰³ In such patients, SPECT-V/Q may be the diagnostic test of choice. If it is unavailable or nondiagnostic, a strategy utilizing duplex ultrasonography and V/Q scanning would appear prudent, followed by selective conventional pulmonary angiography should the noninvasive techniques not yield a definitive diagnosis.

VTE is a leading cause of maternal mortality²⁰⁴; however, given the potential risk of radiation exposure to the fetus,¹⁹⁰ a diagnostic approach that limits that exposure is warranted. Therefore duplex ultrasonography is an appro-

priate initial diagnostic approach. If ultrasonography is negative, the diagnostic evaluation should proceed as previously described on the basis of the clinical assessment probability and using V/Q scanning or SPECT-V/Q as the next diagnostic technique. CTPA has a comparable accuracy to V/Q for pregnancy-associated PE but delivers a higher maternal radiation dose (7.3 mSv for CTPA vs. 0.9 mSv for V/Q).²⁰⁵ However, some data suggest that fetal radiation exposure with CT scanning is comparable or perhaps even lower than with V/Q scanning.^{170,206} (See also Chapter 18.)

PREVENTION OF VENOUS THROMBOEMBOLISM

One of the most striking changes in the field of VTE since the late 1980s has been an emphasis on prevention. This emphasis is totally appropriate and, indeed, should be the cornerstone of modern management. It is clear that if the goal is to prevent PE, the only effective approach is to prevent DVT. The basic information and tools required for developing a prophylactic strategy are now available.

For such a strategy, three fundamentals must be in place: (1) the population at risk must be identified; (2) the duration of the increased thromboembolic risk must be ascertained; and (3) effective, low-risk prophylactic options must be available. Populations at risk of DVT, and therefore of PE, have been identified and such risk can also be quantified as high, moderate, or low. Furthermore, a variety of effective and safe prophylactic approaches are available. It should be emphasized that the trend toward earlier hospital discharge has been accompanied by an increased incidence of post-discharge VTE. Thromboembolic risk does not necessarily end at the time of hospital discharge or of transfer to a lower level of care.²⁰⁷ In patients with an ongoing predisposition to thrombosis at the time of discharge from an acute inpatient setting (e.g., those who underwent major orthopedic, abdominal, or pelvic surgery), prophylaxis should be continued until the risk for VTE has resolved.²⁰⁸

The objective of the prophylactic strategy is to identify the degree of thromboembolic risk in the individual patient and to match the intensity of prophylaxis to that degree of risk. Although a variety of prophylactic approaches have been investigated and utilized, four approaches to the acute phase of treatment have proved effective: low-dose unfractionated heparin, *low-molecular-weight heparin* (LMWH), intermittent pneumatic compression devices, and warfarin.

LOW-DOSE UNFRACTIONATED HEPARIN

Low-dose heparin has been widely studied as a prophylactic modality. Heparin, given subcutaneously in a dose of 5000 units every 8 or 12 hours, is begun as soon as the risk of DVT is evident and is continued until that risk has abated. This regimen has been shown to be effective in reducing the incidence of DVT, PE, and fatal PE in patients at low to moderate risk, such as those undergoing surgical procedures requiring general anesthesia for 30 minutes or longer and with medical conditions requiring bed rest for several

days.²⁰⁹ However, this form of prophylaxis has not been optimally effective in patients whose thromboembolic risk is higher, such as those with hip fracture or hip replacement, those undergoing prostate surgery, and patients suffering major traumatic injuries.²¹⁰ Furthermore, although the bleeding risk of low-dose heparin is nominal in most patients, there are groups of patients in whom heparin administration is contraindicated (e.g., those with active bleeding, hemorrhagic diathesis, and hemorrhagic stroke and those undergoing neurologic or ocular surgery). Patients to be placed on prophylactic heparin should be screened with an initial platelet count, partial thromboplastin time, and prothrombin time. During therapy, however, monitoring of coagulation tests is not useful because such tests do not reflect the safety or efficacy of the regimen. Monitoring of platelet counts on at least a weekly basis would appear to be a prudent option.

LOW-MOLECULAR-WEIGHT HEPARIN

LMWH preparations represent another prophylactic option. In trials that have been performed comparing the prophylactic efficacy of LMWH with unfractionated heparin in general surgical and medical populations, LMWH has not proved superior to unfractionated heparin, although a trend toward decreased bleeding complications associated with LMWH may exist.²¹¹ However, this may simply represent a dose effect. LMWH preparations appear more effective than unfractionated heparin as prophylactic agents in several high-risk groups: patients undergoing hip or knee replacement, patients with spinal cord injury, patients with ischemic strokes, and patients with multiple trauma.^{210,211} LMWH is renally cleared, however, so it must be used with caution in patients with renal insufficiency.

PNEUMATIC COMPRESSION DEVICES

Another extensively evaluated and effective prophylactic approach in low- to moderate-risk patients is the use of mechanical leg compressive devices.^{210,212} These devices periodically (e.g., once or twice per minute) compress the leg by an air-inflatable bladder. A variety of devices are available: thigh-length systems that provide both thigh and calf compression, calf-compressive devices, single-pulse systems, and sequential compression systems. A variety of questions remain unanswered about pneumatic compression devices. For example, it is not known whether the various compressive devices differ in efficacy. It is also unknown whether efficacy depends on strict (24/7) compliance with this intervention during the period of increased thromboembolic risk.^{213,214} However, they appear to reduce the incidence of VTE by about two thirds in most studies.²¹⁵ It is unclear whether pneumatic compression devices are as effective as unfractionated heparin in general medical, surgical, gynecologic, and urologic patients, but they are a useful alternative in patients in whom pharmacologic methods of prophylaxis are contraindicated. The combined use of mechanical prophylaxis and pharmacologic methods in some high-risk patient populations appears to reduce VTE by 50% to 85% more than pharmacologic methods alone.^{212,215,216}

WARFARIN

Warfarin and other “prothrombinopenic” drugs, started like heparin at the onset of high risk (e.g., preoperatively), also have been shown to be effective and safe.²¹⁰ Unfortunately, use of “prothrombinopenic” agents has not gained wide favor as a prophylactic approach. The use of warfarin requires careful monitoring, and there is a perception among physicians that the bleeding risk associated with its use is greater than that reported in the literature. In patients undergoing hip replacement, warfarin has proved effective and has achieved general acceptance. Two regimens are widely used: small doses (1 to 2 mg) given daily for several days before surgery, with dose escalation to therapeutic range, or initiation after surgery.²¹⁷ LMWH preparations appear superior to warfarin, albeit at higher bleeding risk, in patients undergoing knee or hip replacement, with efficacy related, in part, to timing of administration.²¹⁸ It also has become evident that increased thromboembolic risk in patients undergoing hip or knee replacement can extend for 4 to 6 weeks after hospital discharge.²¹⁹ A strategy of extended prophylaxis may be appropriate.²²⁰

FONDAPARINUX

Fondaparinux, a synthetic pentasaccharide that selectively inhibits activated factor X (factor Xa), has been demonstrated in several trials to be effective in the prevention of VTE in patients undergoing lower extremity orthopedic surgery.^{210,221,222} Like unfractionated heparin and LMWH, fondaparinux works by binding to and enhancing the activity of antithrombin. Because of its small size, it enhances antithrombin-mediated inactivation of Xa exclusively. Fondaparinux has almost complete bioavailability and has a longer half-life than LMWH.

DIRECT INHIBITORS OF FACTOR Xa AND OF THROMBIN

Several synthetic oral anticoagulants have recently become available, including rivaroxaban (a specific inhibitor of activated factor X),²²³⁻²²⁶ dabigatran (a direct thrombin inhibitor active against both free and clot-bound thrombin),²²⁷⁻²²⁹ and apixaban (also a specific inhibitor of activated factor X).^{230,231} They have shown varying degrees of promise in randomized controlled trials compared against the LMWH enoxaparin in patients undergoing hip or knee surgery. They appear to be at least noninferior to enoxaparin in this specific population of orthopedic patients in terms of prevention of VTE, with a small but significant trend toward lower associated bleeding risk. However, there are two important considerations relevant to their use. First, there are no specific antidotes if clinically relevant bleeding develops. This is a major limitation to the utility of these drugs for VTE prophylaxis, especially in hospitalized medical patients whose risk of bleeding may be more unpredictable than in orthopedic patients. Second, the increased cost of these newer agents compared with unfractionated heparin and the LMWHs for minimal incremental benefit must be justified before they can be recommended for widespread use.

There is one option available to prevent PE in patients at high risk who cannot be provided pharmacologic or mechanical prophylaxis. Patients with extensive trauma often fall into this category, particularly those with pelvic or lower extremity fractures and internal or intracranial bleeding. In this group, prophylactic placement of an inferior vena cava filter in selected patients provides protection against otherwise nonpreventable emboli.²³²

In summary, given the effective options available, most patients at risk for venous thrombosis can be protected. However, despite this awareness, surveys have demonstrated that prophylaxis is underused in populations at risk.^{233,234} A number of different rationales have been proposed to account for this lack of compliance. The overstated concern for bleeding complications associated with pharmacologic methods of prophylaxis appears to be a deterrent. Furthermore, fatal PE is generally uncommon in any individual physician's experience, thereby diminishing the perception of risk. Finally, the issue of prophylaxis is often subordinated to the compelling demands of the patient's admitting diagnosis and therapy. Whatever the reason, use of prophylaxis must increase if a substantial impact is to be made on the considerable and often unnecessary morbidity and mortality associated with PE. Prophylaxis must not only be applied but also applied in a manner proportionate to the patient's risk of thromboembolism.

MANAGEMENT OF VENOUS THROMBOEMBOLISM

The basic approaches to management are defined chiefly by what is known, as already described, about the pathogenesis, pathophysiology, and natural history of venous thrombosis and PE.

UNFRACTIONATED HEPARIN AND LOW-MOLECULAR-WEIGHT HEPARIN

Heparin, both unfractionated and LMWH, remains the mainstay of therapy for venous thrombosis and for PE not associated with hemodynamic compromise.²³⁵ With a strong suspicion of embolism based on clinical findings and laboratory tests, heparin therapy should be instituted immediately, without awaiting diagnostic confirmation, unless anticoagulation places the patient at significant risk.

Data suggest that physician practices in the administration of unfractionated heparin often result in levels of anticoagulation that fall below those currently recommended in the literature.²³⁶ To overcome these problems, standardized protocols for heparin administration and monitoring have been recommended. A number of different intravenous heparin dosing schemes have been published, all of which have demonstrated the potential to reach a therapeutic threshold more rapidly than a nonstandardized approach.²³⁷ The most widely utilized of these is a weight-based system that includes an 80 unit/kg intravenous bolus of heparin followed by an 18 unit/kg/hr infusion.²³⁸

Whatever regimen is used, an activated partial thromboplastin time (aPTT) is generally obtained 6 hours after the bolus dose, 6 hours after each prescribed dose adjustment,

and then on a daily basis for the duration of therapy. Because maintenance of the aPTT within a rigidly defined range does not appear to increase the efficacy or safety of the drug, frequent dosage adjustments are not necessary once the dose has been stabilized within a therapeutic range. This therapeutic range of aPTT, which corresponds to heparin levels of 0.2 to 0.4 unit/mL by protamine sulfate titration or 0.3 to 0.7 unit/mL by anti-factor Xa assay, may vary substantially depending on the sensitivity of the reagent utilized and among coagulation analyzers.²³⁹ Given the variance in aPTT values possible with different reagents and analyzers, individual institutional validation should be performed to define a therapeutic aPTT value. It also should be recognized that heparin requirements tend to decrease during the course of therapy, resulting in an increase in the level of the aPTT. For patients with heparin resistance (defined as the need for >40,000 units/day), monitoring heparin with an anti-factor Xa assay appears safe and effective and results in less escalation of the heparin dose than monitoring with the aPTT.²⁴⁰

Interestingly, *supratherapeutic* aPTT values are not associated with an increased risk of clinically important bleeding complications.²⁴¹ There is no direct evidence that the absolute dose of heparin or the level of the aPTT can predict the likelihood of bleeding. Instead, bleeding during heparin therapy appears to be related to the presence of concurrent illness such as renal disease, a history of heavy alcohol consumption, aspirin use, and prior surgical procedures or peptic ulcer disease. Thus these data encourage adequate use of heparin doses. In fact, failure to treat patients early with sufficient heparin doses appears to have long-term and short-term implications for thromboembolic recurrence. It is somewhat controversial, however, whether the aPTT level itself, independent of the heparin dose, is associated with higher recurrence rates²⁴² or whether it is strictly a matter of insufficient dosing itself.²⁴³

Subcutaneous LMWHs are widely used for the treatment of VTE because of their high bioavailability and longer half-life, which allows the strategy of dosing once or twice daily, with adjustment for weight but without the need for adjustment by aPTT monitoring.^{235,244} Indeed, the same strategy is appropriate for subcutaneous (unfractionated) heparin as well, administered in high doses. An approach utilizing a fixed dose of subcutaneous unfractionated heparin, administered as an initial dose of 333 U/kg followed by a dose of 250 U/kg every 12 hours, has been demonstrated to be as safe and effective as LMWH in patients presenting with venous thrombosis and PE.²⁴⁵ Clinicians must recognize that the administration of LMWH may not be preferable under certain clinical circumstances. Standardized dosing can be a problem in patients at the extremes of body weight; because the drug is renally cleared, dose adjustments and monitoring with anti-factor Xa levels are necessary in patients with renal insufficiency; the anticoagulant effect of the drug cannot be monitored easily; populations exist (e.g., patients at high bleeding risk) in which a longer drug half-life is not a desirable effect; the ability of protamine sulfate to reverse the anticoagulant effect remains uncertain; and drug costs are substantially higher than with unfractionated heparin.

Clinical trials have demonstrated that the safety and efficacy of LMWH preparations are comparable with those of

unfractionated heparin in patients with venous thrombosis.²⁴⁶ In selected patients, fixed-dose subcutaneous LMWH appears to be safer and more effective than intravenous adjusted-dose unfractionated heparin.²⁴⁷ However, fixed-dose subcutaneous LMWH appears to be comparable with subcutaneous unfractionated heparin, either in adjusted doses^{247,248} or fixed doses.²⁴⁹ Trials have also demonstrated that most patients with acute venous thrombosis can be treated safely on an outpatient basis with LMWH and that outpatient therapy can reduce total medical expenditure.²⁵⁰ However, not all patients with venous thrombosis can or should be treated in an outpatient setting. Approximately 50% of patients are ineligible for outpatient therapy owing to such factors as major bleeding risk, compliance problems, renal failure, significant comorbid disease, inadequate cardiopulmonary reserve, and inaccessibility for follow-up. Furthermore, embolism can happen during the early aspects of therapy in patients treated with both unfractionated and LMWH preparations. Although this circumstance would not be diminished in an inpatient setting, the potential consequences of recurrence, especially in patients with preexisting cardiopulmonary disease, might be more promptly detected and managed in this setting.

The Hestia Study demonstrated the feasibility of outpatient therapy for acute PE patients who are hemodynamically stable (without perceived need for thrombolysis or embolectomy), at low risk for bleeding, not hypoxemic, free of severe liver or kidney dysfunction, without severe pain or other reason for hospital admission and who did not develop PE while on anticoagulants or while pregnant.^{251,252} About one quarter of the patients who met these criteria were briefly admitted for evaluation and discharged in less than 24 hours. The Hestia criteria for outpatient therapy appear to be useful even in patients with CTPA evidence of enlarged right ventricular dimensions, provided they are otherwise hemodynamically stable.²⁵³ Even in patients who require initial inpatient management, the duration of hospitalization can be decreased considerably by a quick transition to outpatient therapy as their conditions stabilize.

In terms of duration of heparin/LMWH therapy, studies have shown that utilizing a 5-day course of therapy in patients with proximal venous thrombosis is associated with a recurrence rate identical to that of a 10-day course.²⁵⁴ This assumes, of course, that warfarin is started early and is in a therapeutic range for 2 consecutive days before heparin is discontinued, a target often difficult to achieve. It is likely that a short course of heparin therapy would be similarly effective in patients with uncomplicated PE. However, a longer course of therapy is advisable in patients with major PE or extensive iliofemoral venous thrombosis.

The major complications of unfractionated heparin and LMWH are bleeding and the development of thrombocytopenia.^{255,256} There are no predisposing factors to heparin-associated thrombocytopenia other than a history of a previous exposure, and it develops at the same frequency with either (unfractionated) heparin or LMWH.²⁵⁷ Two types of thrombocytopenia are associated with heparin administration: an early-onset (1-5 days), non-immune-mediated reduction in platelet count (type I) believed to be secondary to a direct agglutinating effect of heparin on platelets and a late-onset (≥ 4 days), immune-mediated thrombocytopenia (type II) that may be associated with

venous and arterial thrombosis. Immune-mediated thrombocytopenia can also arise within a day of initiating therapy in patients who have been exposed to the drug within the prior 100 days.²⁵⁸ The incidence of thrombosis with heparin-associated thrombocytopenia appears to be low, but when it happens, it is associated with considerable morbidity and mortality. Therefore heparin should be immediately withdrawn if this diagnosis is suspected. If heparin-associated thrombocytopenia type II is confirmed by either a functional assay or an immunoassay, withdrawal of heparin alone may be associated with an adverse outcome.²⁵⁹ A number of therapeutic alternatives exist, including direct thrombin inhibitors (lepirudin or argatroban), which do not react with heparin antibodies, or danaparoid, which appears to have a low rate of *in vivo* cross reactivity with heparin.^{260,261} Cross reactivity between unfractionated heparin and LMWH is relatively common, and these drugs should be avoided.²⁶²

FONDAPARINUX

Fondaparinux is effective and safe for the initial treatment of PE²⁶³ and of DVT.²⁶⁴ The dosing regimen used in these trials was straightforward: 7.5 mg subcutaneously once daily in patients who weighed from 50 to 100 kg (85% of cases). The dose was decreased to 5 mg in patients weighing less than 50 kg and increased to 10 mg in those weighing more than 100 kg. As is the case for unfractionated heparin and LMWH, the treatment was continued for at least 5 days, during which time warfarin was administered. After 5 days and once warfarin was therapeutic, treatment with fondaparinux was stopped. In a double-blinded randomized trial for the treatment of acute proximal lower extremity DVT,²⁶⁴ this regimen was as effective in preventing recurrent symptomatic VTE as enoxaparin, 1 mg/kg body weight twice per day. A randomized, open-label clinical trial compared the same fondaparinux treatment regimen with intravenous unfractionated heparin (using standard aPTT-driven dosage adjustments) for the treatment of pulmonary embolism.²⁶³ The outcomes of the two treatments appeared identical: the fondaparinux and standard therapy groups did not significantly differ with respect to the incidence of recurrent VTE, bleeding, overall mortality, or mortality due to PE. It is noteworthy that fondaparinux may accumulate to dangerous levels in patients with renal insufficiency because of its near total renal clearance.²⁶³⁻²⁶⁵

DIRECT INHIBITORS OF FACTOR Xa AND OF THROMBIN

Rivaroxaban is a synthetic inhibitor of Xa that can be used in the acute phase of VTE treatment. It differs from the parenteral agents (unfractionated, LMWH, and fondaparinux) in that it is a direct inhibitor. For this reason, it does not depend on the body's antithrombin in order to inactivate thrombosis. Another important difference is that it is well absorbed when given orally. Rivaroxaban is safe and effective for the treatment of the acute phase, as well as the 3-month follow-up phase of treatment for PE²⁶⁶ and for DVT.²⁶⁷ However, the acute phase of VTE treatment with rivaroxaban lasts for 3 weeks, as opposed to the shorter acute phase used with parenteral agents.

Figure 57-9 Inferior vena cava filter in place below the renal veins.

The high bioavailability and pharmacokinetic predictability of once- or twice-daily oral rivaroxaban,^{268,269} as well as the safety of using it without the need for adjustment by INR values, is advantageous. Rivaroxaban is cleared by both renal and hepatic routes, including cytochrome P₄₅₀-mediated metabolism. In the trials listed earlier, patients with severe renal or hepatic dysfunction were excluded. There are also potential drug interactions with agents that inhibit cytochrome P₄₅₀ 3A4, such as azole compounds or HIV-protease inhibitors.

INFERIOR VENA CAVA FILTERS

Scientific evidence supporting the use of inferior vena cava filters (Fig. 57-9) is limited.^{270,271} Established indications for filter placement in the therapy of VTE include (1) protection against PE in patients with acute VTE in whom conventional anticoagulation is contraindicated (recent surgery, hemorrhagic cerebrovascular accident, active bleeding, heparin-associated thrombocytopenia, etc.); (2) protection against PE in patients with acute VTE in whom conventional anticoagulation has proved ineffective; and (3) protection of an already compromised pulmonary vascular bed from further thromboembolic risk (massive PE, chronic thromboembolic pulmonary hypertension). In support of the third indication is the recent review of a national inpatient database that disclosed that unstable PE patients who received *inferior vena cava* (IVC) filters had higher survival rates than those who did not receive them.⁴

Mortality from filter placement appears to be quite low regardless of what filter is used.²⁷⁰ Nonfatal complications of IVCs include (1) complications relating to the insertion process, (2) venous thrombosis at the site of insertion, (3) filter migration, (4) filter erosion through the inferior vena cava wall, and (5) inferior vena cava obstruction. The majority of clinically important complications appear to involve venous thrombosis at the insertion site and inferior vena cava obstruction.²⁷¹

Filter placement should not be considered as the sole therapy for VTE unless an absolute contraindication to

anticoagulation exists. Although protecting the pulmonary vascular bed, filter placement does not inhibit the extension of existing venous thrombi or diminish the systemic prothrombotic state. Small thrombi can pass through patent filters or through collaterals around obstructed filters; furthermore, thrombus can extend through the filter itself. One study demonstrated that placement of a vena cava filter was capable of diminishing the incidence of early PE.²⁷¹ The benefit was somewhat offset by an increased risk of recurrent DVT within 2 years, although an 8-year follow-up did not disclose an increased risk of recurrence or postthrombotic syndrome.²⁷² The development of retrievable filters suggests that the intervention will no longer be irreversible, although extensive randomized clinical trials have not yet been performed to establish the safety and efficacy of this strategy.^{273,274} Given these considerations, long-term anticoagulation should be utilized following filter placement if no contraindications exist or as soon as any existing bleeding risk resolves.

MASSIVE PULMONARY EMBOLISM

The significant mortality associated with massive PE justifies a separate consideration of the diagnostic and therapeutic approach to this problem.²⁷⁵ The definition of massive PE should be based on hemodynamic considerations rather than purely anatomic ones. This impression is supported by mortality statistics from the urokinase trials and others.²⁷⁶⁻²⁷⁸ Although anatomically massive emboli have a greater likelihood of being associated with hemodynamic compromise, not all anatomically massive emboli lead to circulatory insufficiency. Irrespective of the degree of vascular obstruction, patients with PE who present with shock have a mortality rate, regardless of the type of intervention, that approaches 30%.

STRATIFICATION ACCORDING TO THE RISK OF MASSIVE PULMONARY EMBOLISM

The risk of mortality and significant morbidity from acute PE is substantially influenced by patient's premorbid conditions and clinical presentation.²⁷⁹ Such risk has been usefully assessed by clinical scoring systems. The *Pulmonary Embolism Severity Index* (PESI), a risk-stratification scoring system derived from patients' demographic characteristics (gender and age), analyzes coexisting illnesses (cancer, heart failure, and chronic lung disease) and physical findings related to cardiopulmonary status (heart rate, systolic blood pressure, respiratory rate, temperature, mental status, and oxygenation).^{280,281} The PESI divides PE patients into five distinct classes of risk, and the mortality associated with each class was remarkably consistent across several validation populations. Mortality was typically between 0% and 1.6% for class I, 2% and 3.5% for class II, 6.5% and 7.7% for class III, 10.4% and 12.2% for class IV, and 17.9% and 24.5% for class V. One small validation population, in which the sickest patients had been excluded, demonstrated about half the mortality for each of the five classes. A simplified version of the PESI score (including only age, cancer,

chronic cardiopulmonary disease, heart rate, systolic blood pressure, and oxyhemoglobin saturation levels) appears to perform just as well as the more complicated one.²⁸² Regardless of the scoring system used, it is important to remember that clinical judgment is paramount. A patient with a low PESI score who nonetheless appears severely ill should be monitored according to clinical judgment, rather than by the score itself.²⁸¹

Echocardiography and other techniques have been investigated as means of stratifying risk in patients with embolism.²⁸³ Short-term mortality risk in PE is strongly related to the presence of systemic hypotension at the time of diagnosis. However, systemic hypotension represents a late and potentially fatal manifestation of right ventricular dysfunction. For this reason, transthoracic echocardiography²⁸³ and biochemical markers such as serum troponin²⁸⁴ or serum brain natriuretic hormone²⁸⁵ levels have been investigated as a means of evaluating right ventricular function in patients with embolism. Clinical studies have suggested that although these techniques are reasonably capable of distinguishing patients with a good prognosis from those at risk for death and other adverse events, they lack the predictive power to warrant clinical decision making exclusively on the basis of a single test.²⁸⁶⁻²⁸⁸ Moreover, it has not been conclusively established that the potential risks of a more aggressive therapeutic approach in all “high-risk” patients, the majority of whom have a satisfactory outcome when treated with conventional therapy alone, justify the potential benefit.²⁸⁹

The therapeutic approach to the patient with hemodynamically massive PE should be designed to counteract the adverse physiologic consequence of pulmonary vascular obstruction, whether or not that obstruction is anatomically massive. Basic care of a critically ill patient should not be overlooked while specific diagnostic and therapeutic considerations are being implemented. Oxygen should be administered to alleviate the hypoxic pulmonary vasoconstriction, which might be contributing to the pulmonary hypertension. Intubation and mechanical ventilatory support might be required to improve oxygenation and decrease metabolic demands. Although volume resuscitation has been advised, excessive preload may further distend the right ventricle and increase right ventricular wall tension, resulting in decreased coronary perfusion and right ventricular ischemia. The judicious use of inotropic support can also prove useful in increasing blood pressure, preserving right coronary artery perfusion, and supporting right ventricular function.²⁹⁰ Although there is a tendency to utilize central hemodynamic monitoring in critically ill hypotensive patients, this intervention should be considered carefully in the patient with massive PE. A femoral approach poses the risk of dislodging residual iliofemoral thrombus, and balloon flotation poses the risk of dislodging embolic material that might be trapped within the right atrial or ventricular cavities (see [Video 57-2](#)).

Although the central goal of therapy in massive PE should be to relieve pulmonary vascular obstruction, the severely compromised nature of the pulmonary vascular bed makes prevention of recurrence an important secondary consideration. Therefore, assuming the requisite expertise in filter placement is available and that placement of a filter will not interfere with the primary management of the

patient, placement of a filter should be considered in all patients with hemodynamically massive embolism.

THROMBOLYTIC THERAPY

The use of thrombolytic agents in acute PE remains controversial.^{291,292} Although thrombolytic therapy with plasminogen-activating medications does appear to accelerate the rate of thrombolysis, there is no convincing evidence to suggest that it decreases mortality, increases the ultimate extent of resolution when measured at 7 days, reduces thromboembolic recurrence rates, improves symptomatic outcome, or decreases the incidence of thromboembolic pulmonary hypertension.²⁹³⁻²⁹⁵ The one issue about which there can be little controversy is that the use of thrombolytic agents is associated with a substantially increased risk of bleeding, including intracranial hemorrhage. Intracranial hemorrhage has developed in 0.5% to 2% of patients treated with thrombolytic agents in trials evaluating the use of these agents in both PE and myocardial infarction.^{294,296}

On the basis of these data, and assuming there is no contraindication to its use, the role of thrombolytic therapy in PE should be limited to those circumstances in which an accelerated rate of thrombolysis may be considered lifesaving (i.e., in patients with PE who present with hemodynamic compromise or who develop hemodynamic compromise during conventional therapy with heparin). In patients with embolism associated with intracavitary right atrial or ventricular thrombi, thrombolytics may be a reasonable consideration, although direct, surgical removal should also be considered.^{297,298} At present, the finding of right ventricular dysfunction on echocardiography in the absence of hemodynamic instability should not serve as a justification for thrombolytic therapy.^{289,291} Approximately one third of patients with PE will have echocardiographic evidence of right ventricular dysfunction²⁹⁹ and there is insufficient evidence to warrant a change in therapy on the basis of that finding alone.²⁸⁸ Unless a subset of patients with right ventricular dysfunction who are at risk for an adverse outcome and benefit from thrombolytic therapy can be identified,³⁰⁰ there is little basis for exposing all such patients to the considerable risk of hemorrhagic complications with thrombolysis. This is especially true given the recent advances in heparin administration strategies.

PULMONARY EMBOLECTOMY

The role of pulmonary embolectomy in acute hemodynamically massive PE also remains controversial.³⁰¹⁻³⁰⁴ Patients with anatomically massive or submassive emboli who are hemodynamically compromised, who have not had a cardiac arrest, and who do not have an absolute contraindication to thrombolytic therapy should be managed initially with aggressive medical therapy, including thrombolytic therapy plus heparin. Patients in whom acute embolectomy might be considered include those with hemodynamically massive PE who have an absolute contraindication to anticoagulant or thrombolytic therapy, those who have suffered a cardiopulmonary arrest (although the mortality associated with embolectomy in those who have

had one is far higher than those who have not), and those in whom aggressive medical therapy, including the use of thrombolytics, has proved ineffective.³⁰⁵

The concept of relieving the pulmonary vascular obstruction and decreasing right ventricular afterload with a percutaneous device has been appealing.³⁰⁶ Catheter-directed therapy for acute PE may be accomplished by mechanical disruption and aspiration, by infusion of plasminogen-activating medications, or both. Uncontrolled (mostly retrospective) clinical studies suggest that catheter-directed thrombolysis may entail less hemorrhagic risk than systemic administration of thrombolytic agents. However, there are no randomized controlled trials to indicate when catheter-directed thrombolysis would result in better outcomes than other forms of therapy.³⁰⁷

POSTEMBOLIC PROPHYLAXIS

After the acute phase of treatment, recurrence is substantially reduced by a follow-up course of anticoagulation for at least 3 months.³⁰⁸ Anticoagulation is typically accomplished with warfarin, adjusted to keep the *international normalized ratio* (INR) of prothrombin time between 2 and 3. In patients with cancer-associated thromboembolism, follow-up therapy with LMWH led to better outcomes than treatment with warfarin.³⁰⁹

Direct inhibitors of factor Xa and of thrombin are promising alternatives to warfarin for follow-up therapy for thromboembolism. Rivaroxaban (described earlier for the acute phase of VTE treatment) has been shown to be safe and effective for follow-up treatment of PE²⁶⁶ and DVT.²⁶⁷ It is well absorbed orally and does not require close therapeutic monitoring or INR values, which are necessary for warfarin treatment.

Dabigatran, a direct thrombin inhibitor, is another alternative to warfarin for the follow-up phases of treatment for venous thromboembolism. Like rivaroxaban, it is a direct inhibitor that does not rely on the patient's antithrombin for its activity. Another similarity is that it is well absorbed orally; it is not, however, recommended for the acute phase of treatment. Dabigatran was comparable with warfarin in a randomized controlled trial for the follow-up treatment of venous thromboembolism.³¹⁰ After acute treatment with heparin or LMWH, patients were randomized to dabigatran, 150 mg orally twice a day without dosage adjustment, or warfarin, adjusted to an INR of 2 to 3. The outcome of the two groups was similar with respect to symptomatic recurrent VTE and major bleeding. These results suggest that dabigatran is an acceptable alternative to warfarin for the 6-month treatment of VTE following acute therapy with heparin or LMWH. It has the advantage of not requiring INR-guided dosage adjustment, which can be labor intensive for clinicians and patients. Dabigatran is well absorbed orally and has a pharmacokinetic profile in most patients that allows dosing for either prophylaxis or treatment of VTE without adjustment in most patients. The simplicity of the dosing regimens suggests that dabigatran would be an attractive option for patients with normal renal and hepatic function. However, clinical trials typically excluded patients with creatinine clearances less than 30 mL/minute and those with severe hepatic enzyme elevations.

The duration of outpatient anticoagulation for patients with PE remains a subject of controversy.^{63,311-314} Much of the difficulty in making definitive recommendations regarding the duration of outpatient anticoagulation results from the diverse population that is affected by the disease process. The decision to continue or withdraw therapy should be made on an individual basis and take into account factors such as the nature of the initial thromboembolic event (spontaneous or associated with a defined clinical circumstance), the type of initial event (venous thrombosis or PE), the presence of an ongoing predisposition (either clinical or hereditary), and possibly the persistence of residual venous thrombosis as determined by ultrasonography or persistently high D-dimer levels in the blood.^{63,65,311-316}

Patients with a clearly defined initial predisposition, whose initial thromboembolic risk factors have resolved and whose V/Q scan and noninvasive lower extremity test results have normalized, can likely be managed with a 3-month course of anticoagulation.³¹⁴ This maxim is especially warranted when the thromboembolism was provoked by surgery.³¹⁷ Patients without a clearly defined initial predisposition to thromboembolism have about a 30% to 50% risk of recurrence during the subsequent 10 years.^{318,319} Those with persistent large lung perfusion defects or abnormal lower extremity test results probably may also have higher rates of recurrence.^{235,311,312} Although the topic is controversial, those patients may benefit from an indefinite period of anticoagulation, even though such a strategy is associated with an increased risk of hemorrhagic complications.³²⁰ Clinical circumstances in which indefinite periods of anticoagulation should be considered quite strongly include a history of more than one episode of idiopathic venous thrombosis or PE; the presence of certain irreversible acquired or hereditary risk factors that strongly predispose toward VTE (active cancer, immobilization, antiphospholipid antibody syndrome, and hereditary deficiencies of antithrombin III, protein C, or protein S³²¹); the presence of extensive residual venous thrombosis or the postthrombotic syndrome; and the presence of extensive residual V/Q scan or CT scan defects or pulmonary hypertension. Although the presence of the heterozygous factor V Leiden mutation or the prothrombin gene mutation individually does not appear to increase the absolute risk of recurrence substantially,¹⁸ the presence of the homozygous factor V Leiden mutation or the heterozygous factor V Leiden mutation in combination with the prothrombin gene mutation does appear to be associated with an increased recurrence risk.³³

A standard for repeating noninvasive testing of either the lungs or the deep veins of the lower extremities at the anticipated time of anticoagulant discontinuation does not exist. Although the cost implications would be substantial, such an approach would be beneficial in establishing a new baseline study that could be used for comparison in the event thromboembolic recurrence was suspected and in identifying patients with pulmonary vascular obstruction of sufficient extent to place them at risk for the development of chronic thromboembolic pulmonary hypertension.

Regarding postembolic anticoagulant "intensity," the recommended therapeutic range for the INR in the majority of patients with VTE is 2 to 3. It is controversial whether patients with the antiphospholipid syndrome should be an

exception to this rule because a retrospective analysis suggested that an INR of 3 to 4 was considered more effective in reducing recurrence rates than an INR less than 3.³²² However, subsequent randomized treatment trials of patients with the antiphospholipid syndrome showed the standard INR target of 2 to 3 to be just as effective as the higher target range.^{323,324} In patients with a lupus anticoagulant, in whom the baseline INR may be elevated, the INR may not reliably reflect the level of anticoagulation. In these patients, the use of tests that are insensitive to the lupus anticoagulant, such as the prothrombin-proconvertin time or chromogenic factor X assay, has been recommended.³²⁵

Trials evaluating the effectiveness of low-intensity anticoagulation (maintaining the INR in a range of 1.5 to 2) following a standard 3- to 6-month period of anticoagulation have demonstrated that such an approach is superior to placebo but less effective than standard therapy, without an appreciable reduction in bleeding complications.^{326,327}

Aspirin is another alternative for extended therapy of unprovoked venous thromboembolism in patients who have completed the standard (acute and several-month follow-up) course of anticoagulation. However, its effectiveness in preventing recurrence was variable in clinical trials and substantially less than what is observed with warfarin. In one trial, aspirin moderately reduced (but did not eliminate) the rate of recurrence,³²⁸ but in a similarly conducted trial, it did not significantly reduce recurrence.³²⁹ In both trials, however, aspirin did not appreciably increase bleeding risk. In addition, the benefits of aspirin on other cardiovascular causes of morbidity and mortality (stroke, myocardial infarction, etc.)³²⁹ make it an attractive option for patients with unprovoked venous thromboembolism who are not candidates for more effective forms of extended anticoagulation therapy.

RESOLUTION VERSUS PERSISTENCE OF THROMBOEMBOLISM

After a PE, the embolic material in the pulmonary arteries either resolves by fibrinolysis or is remodeled into organized scars. The extent of remodeling and the severity of the resulting vascular obstruction varies among patients; in some, lung perfusion is rapidly restored,⁹⁶ although the resolution in the first week is typically incomplete. Embolic remodeling probably continues at a slower pace for the next 1 to 2 months.^{330,331} Residual defects commonly persist beyond this period, suggesting that the emboli have been remodeled into permanent vascular scars.^{69,90-95,332-334}

Although the mechanism is not well understood, restoration of lung perfusion is frequently incomplete.³³⁵⁻³⁴⁶ Persistent perfusion defects are associated with respiratory symptoms,³³⁹ hypoxemia,^{335,340,346} gas exchange deficits,^{340,347,348} exercise intolerance,³⁴⁹ and other serious clinical consequences.^{335,339,340,346-350} Persistent perfusion defects are also associated with worsened *New York Heart Association* dyspnea classification, increased pulmonary artery pressure, and a markedly increased risk of chronic thromboembolic pulmonary hypertension.⁹⁸

CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

In a small percentage of patients, estimated to represent about 0.4% to 3.8% of the 450,000 patients who survive a pulmonary embolic event each year in the United States, the emboli do not resolve and the residual obstruction is sufficient to cause persistent pulmonary hypertension.³⁵¹⁻³⁵⁸

Most patients who present with chronic thromboembolic pulmonary hypertension were previously diagnosed with acute pulmonary emboli or DVT, and their presentations (e.g., embolic burden, clinical stability) appear indistinguishable from patients who do resolve their acute emboli.³⁵¹ A prospective study of patients presenting with PE disclosed that, in addition to the size of the initial PE, factors such as recurrent PE, idiopathic PE, and PE at a young age were associated with an elevated risk for chronic thromboembolic pulmonary hypertension.³⁵⁹ Other clinical factors associated with chronic thromboembolic pulmonary hypertension are right heart strain (e.g., pulmonary artery systolic pressures >50 mm Hg) during the acute PE,^{97,359} advanced age,³⁵⁹ previous splenectomy,^{360,361} the presence of a ventriculoatrial shunt for the treatment of hydrocephalus,^{360,361} and a variety of chronic inflammatory disorders (e.g., osteomyelitis, inflammatory bowel disease).^{360,361} A number of laboratory findings have also been associated with chronic thromboembolic pulmonary hypertension, the most prominent of which is the lupus anticoagulant, which has been reported in 10% to 50% of these patients.^{362,363} Elevated plasma levels of factor VIII,³⁶⁴ lipoprotein (a),³⁶⁵ and even non-O blood groups³⁶⁶ have a statistical association with the development of chronic thromboembolic pulmonary hypertension after an acute PE. However, the prevalence of other thrombophilic tendencies, such as the factor V Leiden mutation, anti-thrombin III, protein C, and protein S deficiency, does not appear to be higher in these patients than that encountered in the normal population.

Despite the epidemiologic associations, the mechanism underlying chronic thromboembolic pulmonary hypertension development remains unclear.³⁶⁷ A subset of patients appears to have an intrinsic resistance to fibrinolysis.³⁶⁸ The resistance is associated with abnormalities in fibrinogen that alter its molecular structure.^{369,370} Such alterations in fibrinogen likely deform and disorganize the fibrin polymer networks, thereby making them more resistant to fibrinolysis and perhaps stimulating remodeling of thromboemboli into scars.

In about half of the patients, the initial acute pulmonary thromboembolism is not clinically recognized.³⁷¹ The diagnosis of thromboembolic pulmonary hypertension is usually not made until the degree of pulmonary hypertension is advanced. As a result, the exact hemodynamic evolution of the disease has not been fully established.³⁷² The extent of pulmonary vascular obstruction appears to be a major determinant of disease initiation, with involvement of greater than 40% of the pulmonary vascular bed present in the majority of patients. Hemodynamic progression in certain patients may involve thromboembolic recurrence or in situ pulmonary artery thrombosis. However, hemodynamic progression in many patients appears to involve the

development of a hypertensive pulmonary arteriopathy, similar to that encountered in other causes of secondary pulmonary hypertension.³⁷³ This supposition is supported by several lines of evidence: a poor correlation between the extent of central anatomic obstruction and the degree of pulmonary hypertension; documented hemodynamic progression in the absence of recurrent embolic events or evidence of *in situ* pulmonary artery thrombosis; and histopathology demonstrating arteriopathic changes in the resistance vessels of both the involved and uninvolved pulmonary vascular system.

Survival without intervention is poor and proportional to the degree of pulmonary hypertension at the time of diagnosis. In one study, the 5-year survival rate was 30% when the mean pulmonary artery pressure exceeded 40 mm Hg and 10% when it exceeded 50 mm Hg.³⁷⁴ In another study, a mean pulmonary artery pressure above 30 mm Hg appeared to serve as a threshold value portending a poor prognosis.³⁷⁵

DIAGNOSIS

Perhaps the most important aspect of dealing with this patient group is the proper approach to its recognition.³⁷⁶ Progressive dyspnea is a complaint common to all patients with chronic thromboembolic pulmonary hypertension. Later in the course of the disease, exertional chest pain, near-syncope or syncope, or lower extremity edema may develop.

Although a history of documented thromboembolism may not be present, many patients can provide a history consistent with an acute embolic event. They may describe an episode of “pleurisy,” lower extremity “muscle strain,” or prolonged, atypical “pneumonia,” or they may describe a hospitalization or surgical procedure from which they never fully recovered. That an episode of VTE was not diagnosed, or was misdiagnosed, is not surprising because venous thrombosis and PE are often overlooked.³⁷⁷

Diagnosis is commonly delayed, particularly in the absence of an acute history of VTE. Progressive dyspnea and exercise intolerance are often attributed to coronary artery disease, cardiomyopathy, interstitial lung disease, asthma, deconditioning, or psychogenic dyspnea. Therefore an abnormality of the pulmonary vascular bed should be considered in any patient with dyspnea in whom a definitive etiology cannot be defined. Later in the course of the disease, the patient may experience exertional chest pain, presyncope, or syncope due to the presence of severe pulmonary hypertension and the inability of a compromised right ventricle to meet cardiac output demands.

Physical examination findings may be subtle early in the course of the illness, thereby contributing to this diagnostic delay. Before the development of significant right ventricular hypertrophy or overt right ventricular failure, physical examination abnormalities may be limited to a narrowing of S2 or to a subtle accentuation of its pulmonic component. Late in the course of the disease, obvious findings such as a right ventricular heave, jugular venous distention, prominent a- and v-wave venous pulsations, fixed splitting of S2, a right ventricular S3, murmurs of tricuspid regurgitation or pulmonic insufficiency, hepatomegaly, and ascites may develop. Peripheral edema, a result of chronic

lower extremity venous outflow obstruction or right ventricular failure, may be present.

A unique physical finding in certain patients with chronic thromboembolic disease is the presence of flow murmurs over the lung fields.³⁷⁸ These subtle bruits, which appear to originate from turbulent flow through partially obstructed or recanalized thrombi, are high pitched and blowing in quality, heard over the lung fields rather than the precordium, accentuated during inspiration, and frequently heard only during periods of breath-holding. These bruits have not been described in primary pulmonary hypertension, the most common competing diagnostic possibility.

The intent of the diagnostic evaluation is to establish the presence and degree of pulmonary hypertension, define its etiology, and, if major vessel thromboembolic disease is present, determine whether it is accessible to surgical intervention. Findings on standard laboratory tests are nonspecific, depending on the point in the natural history of the disease at which they are obtained, and reflective of the hemodynamic and gas-exchange consequences of the thromboembolic obstruction and the accompanying cardiac dysfunction.

Chest radiography, although often normal, may demonstrate findings that suggest the diagnosis.³⁷⁹ Enlargement of both main pulmonary arteries or asymmetry in the size of the central pulmonary arteries may be present (Fig. 57-10). Areas of hypoperfusion or hyperperfusion may be present. There also may be evidence of old pleural disease, unilaterally or bilaterally. The cardiac silhouette may reflect obvious right atrial or right ventricular enlargement; more often, right ventricular hypertrophy and enlargement are suggested only on the lateral image by encroachment on the normally empty retrosternal space.

Early in the course of the disease, electrocardiographic findings may be normal. Later in the course, electrocardiography demonstrates evidence of right ventricular hypertrophy. Pulmonary function testing, performed to evaluate the patient's dyspnea, is often within normal limits. The majority of patients have a reduction in the single-breath diffusing capacity for carbon monoxide; however, a normal value does not exclude the diagnosis. Approximately 20% of patients demonstrate a mild to moderate restrictive defect due in part to the presence of infarct-related parenchymal scars.³⁸⁰ However, the degree of spirometric defect is almost always disproportionate to the patient's gas-exchange abnormalities, symptomatic complaints, and degree of pulmonary hypertension.

In terms of gas-exchange findings, the arterial PO₂ may be within normal limits. However, the alveolar-arterial PO₂ difference is typically widened, and the majority of patients have a decline in the arterial PO₂ with exercise. Dead-space ventilation is often increased at rest and worsens with exercise. Minute ventilation is typically elevated as a result of this increased dead-space ventilation.³⁸¹

Echocardiography commonly provides the initial objective evidence that pulmonary hypertension is present. Once the diagnosis of pulmonary hypertension has been established, determination of whether it originates from abnormalities of the small, resistance vessels or from central, chronic thromboembolic obstruction is essential.

V/Q lung scanning appears to provide an excellent, noninvasive means of distinguishing between potentially

Figure 57-10 Chest radiograph in a patient with chronic thromboembolic pulmonary hypertension. A, Note asymmetry of central pulmonary arteries, absence of descending left pulmonary artery, left lower lobe oligemia, and peripheral opacity representing prior infarct. **B,** Angiogram in the same patient demonstrates complete proximal occlusion of the descending left pulmonary artery.

operable major vessel thromboembolic pulmonary hypertension and small vessel pulmonary hypertension.^{382,383} In chronic thromboembolic disease, at least one (and, more commonly, several) segmental or larger mismatched V/Q defects are present. In primary pulmonary hypertension, perfusion scans are either normal or exhibit a “mottled” appearance characterized by subsegmental defects. Other disorders leading to pulmonary hypertension may be associated with segmental defects on perfusion scan, including pulmonary veno-occlusive disease, pulmonary artery sarcoma, mediastinal fibrosis, and large vessel vasculitides.³⁸⁴ It is important to recognize that the V/Q often understates the actual extent of central pulmonary vascular obstruction (see eFig. 57-11).³⁸⁵ Channels through central obstructing lesions or partial flow around them, a result of the often complex patterns of recanalization and organization that take place following an embolic event, allow the radioisotopic agent to reach the periphery of the lung. Depending on the distribution of flow, these areas may appear normal or as relatively hypoperfused “gray zones.” Therefore V/Q scanning, although capable of suggesting the potential presence of chronic thromboembolic obstruction, is incapable of determining the magnitude, location, or proximal extent of the disease, information critical to the question of surgical accessibility.

The role of CT scanning in the evaluation of patients with chronic thromboembolic disease is evolving.^{386,387} A variety of CT abnormalities (eFig. 57-12) have been described: chronic thromboembolic material located in an eccentric position within the central pulmonary arteries, right ventricular enlargement, dilated central pulmonary arteries, bronchial artery collateral flow, parenchymal abnormalities consistent with prior infarcts, and mosaic

attenuation of the pulmonary parenchyma.³⁸⁸ However, the absence of these findings does not preclude the possibility of surgically accessible chronic thromboembolic disease. Furthermore, the presence of central thrombus has been described in primary pulmonary hypertension and other chronic pulmonary disorders.³⁸⁹ CT scanning is also incapable of providing essential hemodynamic data. CT is particularly useful in the evaluation of the main pulmonary arteries and of unilateral or predominantly unilateral pulmonary vascular obstruction as determined by V/Q scanning.³⁸⁸ Under these circumstances, the probability of other diagnostic possibilities such as pulmonary artery sarcoma (see Fig. 54-5, eFigs. 54-15, 54-16 and 54-17), vasculitis, malignancy, and mediastinal fibrosis (see eFigs. 37-1A-G and 54-7, 54-21 and 54-22) is increased. CT also has a role, along with physiologic testing, in helping to evaluate the status of the pulmonary parenchyma in patients with coexisting obstructive or restrictive lung disease.

Right-heart catheterization and pulmonary angiography are essential to designate the degree of pulmonary hypertension, exclude competing diagnoses, and define the surgical accessibility of the obstructing thrombotic lesions. If hemodynamic measurements at rest demonstrate only modest degrees of pulmonary hypertension, measurements should be obtained following a short period of exercise. In patients with chronic thromboembolic obstruction sufficient to abolish normal compensatory mechanisms, exercise-related increases in cardiac output will be accompanied by an almost linear elevation in pulmonary artery pressure. The angiographic findings in chronic thromboembolic disease bear little resemblance to the sharply defined, intraluminal defects diagnostic of acute embolism.³⁹⁰ Five distinct angiographic patterns that correlate with the

Figure 57-11 Right-sided pulmonary angiogram in a patient with chronic thromboembolic pulmonary hypertension. Many of the classic angiographic findings associated with this disease are present, including pouch defects (arrow 1), intimal irregularity (arrow 2), pulmonary artery webs (arrow 3) with poststenotic dilation, and complete obstruction (arrow 4) to flow of the right middle lobe and several lower lobe segmental arteries.

finding of organized thromboembolic material at the time of thromboendarterectomy have been described (Fig. 57-11): (1) pouch defects, (2) pulmonary artery webs or bands, (3) intimal irregularities, (4) abrupt narrowing of the major pulmonary arteries, and (5) obstruction of lobar or segmental vessels at their point of origin, with complete absence of blood flow to pulmonary segments normally perfused by those vessels.

Although pulmonary angiography usually completes the diagnostic sequence and confirms surgical accessibility, adjunctive studies may be necessary to exclude competing diagnoses. CT of the chest can be useful in determining whether a mediastinal process (e.g., mediastinal fibrosis, malignancy) is responsible for the angiographic findings and, in selected cases, in defining the extent and accessibility of the obstructing thrombi. Arch aortography can be useful if an arteritis is being considered.³⁹¹

The major conditions from which thromboembolic pulmonary hypertension must be distinguished include primary pulmonary hypertension and other forms of secondary pulmonary hypertension such as mediastinal fibrosis with pulmonary arterial or venous obstruction, pulmonary hypertension associated with congenital atrial or ventricular septal defects, congenital pulmonary artery branch stenoses, pulmonary artery agenesis, tumors arising in or obstructing the central pulmonary arteries, and

Takayasu arteritis. The standard diagnostic approaches previously discussed, preferably performed at a center experienced in the management of pulmonary hypertension, are capable of excluding the majority of these competing diagnoses.

TREATMENT

For patients suffering from chronic thromboembolic pulmonary hypertension, the decision to proceed to pulmonary thromboendarterectomy is based on both objective and subjective factors, which are carefully defined during the preoperative evaluation.³⁹²

Pulmonary thromboendarterectomy is considered in symptomatic patients with hemodynamic or ventilatory impairment at rest or with exercise. The mean pulmonary vascular resistance in patients undergoing surgery is typically 800 to 1000 dyne·sec·cm⁻⁵, with a range of 300 to 2000 dyne·sec·cm⁻⁵.³⁷² Patients in the lower range of pulmonary hemodynamic impairment include those with involvement limited to one main pulmonary artery, those with vigorous lifestyle expectations in whom high dead-space and minute ventilatory demands are disabling, and those who live at altitude. Thromboendarterectomy is also considered in patients with normal or near-normal pulmonary hemodynamics at rest who develop significant levels of pulmonary hypertension with exercise. If surgery is deferred in patients with this hemodynamic profile, careful monitoring is recommended to detect whether pulmonary hypertension progresses.

The location and extent of the proximal thromboembolic obstruction is the most critical determinant of operability. Occluding thrombi must involve the main, lobar, or proximal segmental arteries. Those that originate more distally are not amenable to thromboendarterectomy with current surgical techniques. In terms of extent, the anatomic and hemodynamic findings must be interpreted in concert. An acceptable postoperative hemodynamic outcome requires that the preoperative hemodynamic impairment be consistent with the magnitude of surgically accessible thromboembolic material determined by angiography. This determination is critical. If the major component of the preoperative hemodynamic impairment derives from surgically inaccessible disease or from the resistance conferred by a secondary, small vessel arteriopathy, residual pulmonary hypertension will be present postoperatively. Depending on the extent of the postoperative pulmonary hypertension, this outcome may be associated with adverse short-term and long-term consequences.

The only absolute contraindication to thromboendarterectomy is the presence of severe underlying lung disease, either obstructive or restrictive. Thromboendarterectomy in this population can improve the hemodynamic profile but may have little effect on the ventilatory impairment. Advanced age, severe right ventricular failure, and the presence of collateral disease influence risk assessment but do not represent absolute contraindications to the procedure if the anticipated relief of the pulmonary hypertension will improve both the quality and duration of life. Patients as young as 16 and as old as 84 years of age, as well as those with complex comorbid conditions, have successfully undergone the procedure.

Before surgery, several other essential issues must be considered. It is important that the patient be protected against embolic recurrence, both over the long term and during the high-risk perioperative period. Therefore an inferior vena cava filter should be placed before surgery unless there is an obvious source of embolism outside the lower extremities or pelvis. For those at risk of coronary artery disease, coronary angiography is routinely performed before surgery, usually at the time of the right heart catheterization and pulmonary angiography. Coronary artery bypass grafting, if necessary, can be performed safely at the time of the thromboendarterectomy.³⁹²

Sternotomy with cardiopulmonary bypass and periods of circulatory arrest represents the procedure of choice.³⁹³ This approach allows access to both pulmonary arteries and ensures more complete removal of the chronically obstructing material.³⁹⁴ A sternotomy approach also provides adequate exposure for additional procedures that need to be performed. In a review of 1190 patients undergoing thromboendarterectomy, 90 patients (7.6%) required such a combined procedure exclusive of solitary closure of a patent foramen ovale, which is performed in approximately 30% of thromboendarterectomy procedures.³⁹² The use of cardiopulmonary bypass allows periods of complete circulatory arrest, which provide a bloodless operative field essential for meticulous lobar and segmental dissections.

Thromboendarterectomy bears little resemblance to acute pulmonary embolectomy. The neointima in chronic thromboembolic disease is deceptive and is often not easily recognizable as chronic thrombus. The procedure is a true endarterectomy that requires careful dissection of chronic endothelialized material from the native intima to restore pulmonary arterial patency. Considerable experience is required by the surgical team to identify the correct operative plane and remove the segmental-level extensions of the more proximal obstruction (Fig. 57-12). Failure to do so results in an inadequate hemodynamic outcome.

During the development of and early experience with this procedure, mortality was related to many causes. At present, the major causes of death have been related to

Figure 57-12 Specimen obtained at the time of pulmonary thromboendarterectomy. In addition to central thromboembolic obstruction, note multiple segmental extensions. Failure to remove these distal extensions adequately will result in an inadequate hemodynamic outcome. (From Marshall PS, Kerr KM, Auger WR: Chronic thromboembolic pulmonary hypertension. *Clin Chest Med* 34:779–797, 2013. Fig. 5.)

reperfusion pulmonary edema and to residual postoperative pulmonary hypertension and right ventricular failure in patients in whom pulmonary thromboendarterectomy failed to achieve substantial improvement in pulmonary hemodynamics.³⁹⁴

Although pulmonary hemodynamics may improve immediately, the postoperative course can be complex. In addition to complications common to other forms of cardiac surgery (e.g., arrhythmias, atelectasis, wound infection, pericardial effusions, delirium), patients undergoing pulmonary thromboendarterectomy often experience two unique complications capable of significantly impairing gas exchange: reperfusion pulmonary edema and pulmonary artery “steal.”^{395,396}

Pulmonary artery steal (Fig. 57-13) represents a postoperative redistribution of pulmonary arterial blood flow away from previously well-perfused segments and into the newly endarterectomized segments. Long-term follow-up has demonstrated that pulmonary vascular steal resolves in the majority of patients.³⁹⁷ Reperfusion pulmonary edema appears to represent a form of high-permeability lung injury that is limited to those areas of lung from which proximal thromboembolic obstructions have been removed (Fig. 57-14). It may appear up to 72 hours after surgery and is highly variable in severity, ranging from a mild form of edema resulting in postoperative hypoxemia to an acute, hemorrhagic, and fatal complication. When associated with pulmonary artery steal, reperfusion pulmonary edema can represent a significant challenge in terms of postoperative gas exchange. Pulmonary blood flow is directed toward edematous, noncompliant areas of lung that contribute poorly to gas exchange. Management of reperfusion edema, as with other forms of acute lung injury, is supportive.

Although exact figures are not available, approximately 5000 to 6000 thromboendarterectomy procedures have been performed worldwide, with 3000 of these cases performed at University of California, San Diego. In reported series of patients undergoing thromboendarterectomy since 1999, in-hospital mortality rates have ranged between 4.4% and 21.4%.^{394,398–402} In an update of the University of California, San Diego experience, the mortality for the last 500 patients was 2.2%.⁴⁰³ The specific factors affecting perioperative mortality have not been completely defined. Several studies have suggested that New York Heart Association functional class IV status, age older than 70, the severity of preoperative pulmonary vascular resistance, the presence of right ventricular failure as manifested by high right atrial pressures, details of the postoperative management, and perhaps the duration of pulmonary hypertension may adversely influence outcome. It is also reasonable to suggest that there may exist a strong relationship between volume of procedures performed and outcome, as has been demonstrated with other high-risk surgical procedures.⁴⁰⁴ In the case of thromboendarterectomy, this may be related to consistency of patient evaluation, surgical experience, uniform delivery of postoperative care, and the presence of dedicated resources for dealing with postoperative complications. Should this prove to be the case, strong consideration could be given to performing the procedure at a limited number of referral centers.

Given what is known about the natural history of the disease and the progressive nature of the pulmonary

Figure 57-13 Perfusion scans show pulmonary artery steal. On the left, preoperative perfusion scan demonstrates minimal flow to the left lung. On the right, perfusion scan obtained in the early postoperative period demonstrates dramatic reversal of flow with vascular “steal” from right lung. Equilibration and normalization of flow over time is the rule.

Figure 57-14 Chest radiograph shows postoperative reperfusion pulmonary edema. Only the upper lobes, from which no thromboembolic material was dissected, are spared.

hypertension associated with it, these findings suggest that early referral is preferable to late unless the possibility of a recent embolic event exists. Under this circumstance, a period of 6 to 8 weeks of conventional therapy is recommended to allow optimum thrombus resolution. Beyond

this period, further improvement in the level of pulmonary hypertension cannot be achieved with medical therapy alone.⁹⁷

Among survivors of thromboendarterectomy, restoration of pulmonary artery patency results in an immediate and dramatic hemodynamic improvement (Fig. 57-15). In published series, the mean reduction in pulmonary vascular resistance has approximated 70%, and a pulmonary vascular resistance in the range of 200 to 350 dyne·sec·cm⁻⁵ can be achieved. The long-term hemodynamic and symptomatic outcomes have been equally dramatic. Many patients are restored to normal activity, the majority return to class I functional status, and essentially all have improved at least one grade in the classification of cardiac disability.⁴⁰⁵⁻⁴⁰⁷ Anticoagulation is continued lifelong in order to prevent recurrence. Approximately 10% to 15% of patients undergoing thromboendarterectomy will have residual levels of pulmonary hypertension after the procedure that have been associated with a negative long-term outcome. One therapeutic option for patients who have undergone thromboendarterectomy with an inadequate hemodynamic outcome and for those not deemed candidates for thromboendarterectomy is lung transplantation. Preliminary results suggest that patients who are not considered candidates for thromboendarterectomy and those with residual pulmonary hypertension following the procedure may benefit from medical therapy including prostanoids, endothelin receptor antagonists, and phosphodiesterase inhibitors.⁴⁰⁸⁻⁴¹¹ Epoprostenol has been used preoperatively in patients with chronic thromboembolic pulmonary hypertension associated with severe hemodynamic impairment and has been

Figure 57-15 Pulmonary angiography before and after thromboendarterectomy. **A**, Preoperative pulmonary angiogram shows thromboembolic obstruction involving the right upper, middle, and lower lobe arteries. **B**, Postoperative angiogram shows near-normalization of flow. This angiographic improvement was accompanied by a corresponding hemodynamic improvement.

demonstrated to improve the hemodynamic profile.⁴¹² Whether such an approach improves outcome or decreases the incidence and severity of postoperative complications has not been determined.

Limited observational data suggest a potential role for percutaneous pulmonary balloon angioplasty in selected patients with inoperable chronic thromboembolic pulmonary hypertension.⁴¹³⁻⁴¹⁵ Percutaneous balloon angioplasty carries significant risk of reperfusion injury, cerebral and systemic embolism, and pulmonary artery perforation. Further study is necessary before it is used outside of specialized centers.

Supplemental information about other forms of embolism including schistosomiasis, air and fat embolism, amniotic fluid embolism, and septic embolism are available online at ExpertConsult.

Key Points

- Pulmonary embolism from deep venous thrombosis is an extremely important and still underrecognized cause of morbidity and mortality.
- Morbidity and mortality from pulmonary embolism will only be reduced by the widespread use of prophylactic measures in populations at risk and by a heightened clinical suspicion and awareness of the often subtle and nonspecific presentation of the disease.
- Appropriate use of anticoagulants decreases the risk of further thrombosis and recurrent embolism. Newer agents include direct inhibitors of factor Xa and of thrombin.

- Remaining uncertainties that need resolution include risk stratification in patients with confirmed embolism; the choice among treatment options for patients with unstable pulmonary embolism; selection of populations in which outpatient management is feasible; and prediction of the risk for development of chronic thromboembolic pulmonary hypertension.
- Chronic thromboembolic disease may develop in up to 4% of those with acute pulmonary embolism. Recognition is important because surgical thromboendarterectomy can improve hemodynamics and quality of life. Less invasive options such as percutaneous angioplasty may have a role in selected patients at specialized centers.

OTHER FORMS OF EMBOLISM

Because the lungs receive all of the blood flow returned from the venous system, the pulmonary vascular bed serves as a “sieve” for all particulates entering the venous blood and is the first vascular bed to be exposed to any toxic substance injected intravenously. As a result of its strategic position, the pulmonary vascular bed is therefore exposed to a wide variety of potentially obstructing and injurious agents.

SCHISTOSOMIASIS

Among such agents, the most common on a worldwide basis, although not within the United States, is schistosomiasis.⁴¹⁶ This parasitic disorder may cause pulmonary hypertension by three mechanisms: anatomic obstruction by the organism itself, an intense inflammatory vasculitic response to the components of the organism, and the development of portopulmonary hypertension. In endemic areas, schistosomal disease is the most common cause of cor pulmonale. Limited data suggest that cardiopulmonary schistosomiasis is seen most often in *Schistosoma mansoni* infection. This form of cor pulmonale is always seen with concomitant schistosomal liver disease because the liver is always involved, usually quite extensively, before the lung. The premortem diagnosis of cardiopulmonary schistosomiasis depends on serology and the detection of schistosomal ova in stool or urine along with evidence of hepatic fibrosis and pulmonary hypertension. Treatment with praziquantel can eradicate schistosomal infections with minimal toxicity. However, cardiopulmonary manifestations are not likely to be reversible once chronic fibrosis develops (see Chapter 39).

AIR EMBOLISM

An increasingly common form of nonthrombotic embolism in the United States is air embolism.⁴¹⁷ The increasing frequency of the problem reflects the wide variety of invasive surgical and medical procedures now available (see eFig. 19-2), the broad use of indwelling central venous catheters, the use of positive-pressure ventilation with high levels of positive end-expiratory pressure, and the frequency of thoracic and other forms of trauma.⁴¹⁸ The simple inadvertent transection or disconnection of a large-bore intravenous catheter (eFig. 57-13), particularly in the jugular or subclavian vein, can result in ingress of substantial quantities of air. Air bubbles enter the pulmonary vascular bed and, from there, are diffusely distributed throughout the body either by way of an intracardiac shunt or, more likely, through microvascular pulmonary shunts.

Physiologic consequences of pulmonary air embolism include an abrupt rise in pulmonary artery pressure. Increased permeability (noncardiogenic) pulmonary edema may develop, lung compliance falls, and hypoxemia ensues. The symptoms of air embolism are variable and nonspecific and may include alterations in sensorium, chest pain, dyspnea, or a sense of impending doom. These and other consequences appear to be due to two phenomena: actual lodgment of the bubbles in capillary beds, which interferes

with nutrient supply to the affected organs; and the formation of platelet-fibrin aggregates, creating diffuse microthrombi.⁴¹⁹ Thrombocytopenia may be seen as a consequence of this latter event. The most serious consequences result from cerebral or coronary artery air embolism, the severity of the consequences depending on the volume of air that gains access to the venous circulation.⁴¹⁷

The best approaches to air embolism are prevention and early detection. Treatment consists of measures designed to restore blood flow and to promote reabsorption of the intravascular air. Measures designed to restore flow include patient positioning (Trendelenburg position with the left side down), removal of air through central venous catheters or direct needle aspiration, and closed-chest cardiac massage. Measures designed to increase absorption include the use of 100% oxygen and the institution of hyperbaric oxygen therapy as early as possible.^{420,421} Utilizing such aggressive measures, mortality from air embolism has been dramatically reduced.

FAT EMBOLISM

Another reasonably frequent and dramatic form of nonthrombotic embolism is fat embolism.⁴²² A rather characteristic syndrome follows entry of neutral fat into the vascular system, consisting of the onset of dyspnea, petechiae, and mental confusion. There is a variable lag time of 24 to 48 hours in the onset of the syndrome following the inciting event.

By far the most common inciting event is traumatic fracture of marrow-containing long bones; the incidence of fat embolism rises with the number of fractures. However, orthopedic procedures and trauma to other fat-laden tissues (e.g., fatty liver) are occasionally followed by the same syndrome.

The reasons for the variability in incidence of the syndrome after apparently comparable injuries are not clear. Perhaps variations in incidence and severity relate to the amount of fat released. The pathophysiologic consequences appear to derive from two events: (1) actual vascular obstruction by neutral particles of fat and (2) the injurious effects of free fatty acids released by the action of lipases on the neutral fat.⁴²³ The latter effect is probably the more important, causing a diffuse vasculitis with leakage from cerebral, pulmonary, and other vascular beds.⁴²⁴

The diagnosis of fat embolism syndrome is a clinical one suggested by the onset of dyspnea, neurologic abnormalities, petechiae, and fever in the proper clinical context (see eFig. 94-2).⁴²⁵ Petechiae, typically distributed over the head, neck, anterior chest, and axillae, are present in only 20% to 50% of cases.⁴²⁶ Therefore their absence should not preclude consideration of the disease. No laboratory test is diagnostic of the syndrome.

Although a variety of treatments have been suggested (e.g., intravenous ethanol, albumin, dextran, heparin), none has proved effective. There is some evidence to suggest that corticosteroid therapy might prevent the onset of fat embolism syndrome after an inciting event, but controlled studies are sparse and the topic remains controversial.⁴²⁷ Supportive treatment, including mechanical ventilatory support, when necessary, is the primary approach and, with meticulous supportive care, survival is now the rule.

AMNIOTIC FLUID EMBOLISM (see Chapter 96)

Another special form of embolism is amniotic fluid embolism, a rare but unpredictable and catastrophic complication of pregnancy that represents the third leading cause of maternal mortality.^{428,429} This disorder may arise during or after delivery when amniotic fluid gains access to uterine venous channels and, from there, to the pulmonary and general circulations. The delivery may be either spontaneous or by Caesarean section; there are case reports of amniotic fluid embolism following therapeutic abortion. Unexpectedly and suddenly, the patient may have severe respiratory distress, cyanosis, hypotension, and often, cardiovascular collapse. Although obstruction of the pulmonary vascular bed may exist, the major hemodynamic impairment appears to be related to left ventricular dysfunction.⁴³⁰ Most cases develop during labor (see Fig. 96-6), but delayed onset of symptoms up to 48 hours after delivery has been reported.⁴³¹ Induction of labor, multiparity, advanced maternal age, ethnic minority women, Caesarian delivery, placental abnormalities, eclampsia, polyhydramnios, cervical lacerations, uterine rupture, premature placental separation, fetal death, and meconium staining of amniotic fluid are associated with increased risk of amniotic fluid embolism.^{432,433}

Amniotic fluid contains particulate materials that can cause pulmonary vascular obstruction, but the major pathogenetic mechanism of the syndrome remains uncertain. Amniotic fluid does have thromboplastic activity that leads to extensive fibrin deposition in the lung vasculature and, occasionally, in other organs. Pulmonary vascular resistance can rise, leading to right ventricular failure and shock.⁴³³

As a consequence of fibrin deposition, a severe consumptive coagulopathy develops, including marked hypofibrinogenemia and thrombocytopenia. After the acute event, an enhanced fibrinolytic state often exists.^{426,434}

The diagnosis of amniotic fluid embolism is based on a compatible clinical picture, often enhanced by finding amniotic fluid components in the pulmonary circulation. The presence of squamous cells in pulmonary arterial blood, once considered pathognomonic, has proved to be a nonspecific finding.⁴²⁸

Although various forms of therapy have been suggested (e.g., antifibrinolytic agents such as aminocaproic acid, cryoprecipitate, factor VIIA, pulmonary vasodilators), the best approach is supportive.⁴³³ Even in the setting of aggressive supportive measures, however, maternal mortality is in the range of 60% to 80%, with many survivors suffering from long-term neurologic disability.

SEPTIC EMBOLISM

Septic embolism is another special disorder that, unfortunately, is also increasing in frequency owing to widespread injection drug use and the expanding use of indwelling intravenous catheters. Previously, septic embolism was almost exclusively a complication of septic pelvic thrombophlebitis secondary to both septic abortion and postpuer-

peral uterine infection. Although these conditions still lead to septic emboli, injection drug use is now by far the more common cause.⁴³⁵ An increasingly common cause is iatrogenic: infections secondary to indwelling catheters inserted for a variety of diagnostic or therapeutic purposes.^{436,437}

Microscopically, septic phlebitis consists of purulent material admixed with fibrin thrombus. Embolization can result in obstruction of small pulmonary vessels, but the major consequence is pulmonary infection. Characteristically, imaging shows peripherally distributed pulmonary nodular opacities that undergo cavitation (eFig. 57-14A-G). An increasing number of such opacities develop over periods of hours to a few days. Symptoms and signs include a septic temperature course, dyspnea, cough, pleuritic chest pain, and hemoptysis. Initial treatment consists of appropriate antimicrobial drugs. If an indwelling catheter is suspected to be the source of the infection, it should be removed. If there is not a prompt response to this regimen, surgical isolation of the septic vein, if present, should be considered. The role of systemic anticoagulation remains uncertain. Endocarditis may complicate septic phlebitis or mimic it, particularly in drug addicts.

OTHER EMBOLI

Because of its sieve function, the lung may also be embolized on occasion by a wide variety of other materials.⁴³⁸ Cancer cells, of course, often find their way into and adhere to the pulmonary vessels; on occasion, tumor emboli (admixture of thrombus with cells) can form and mimic bland embolization (see eFigs. 55-2 and 55-3). Trophoblastic tissue can escape the uterus and lodge in the pulmonary circulation during evacuation of a molar pregnancy or during hysterectomy for an invasive mole. After head trauma, brain tissue has been found in the lungs; the same is true of liver cells following abdominal trauma and of bone marrow after cardiopulmonary resuscitation. In rare instances, iatrogenic emboli can arise from injection therapy (e.g., treatment of gastric varices) or even procedures such as vertebroplasty (eFigs. 57-15 and 57-16).

Pulmonary artery thrombi, either from thromboembolism or in situ thrombosis, are found in 10% to 20% of patients with acute chest syndrome from sickle cell crisis (see Chapter 94).⁴³⁹ During acute chest syndrome patients, pulmonary artery thrombosis may present without clinical findings suggestive of PE in other patient populations, so clinicians would be wise to have a high index of suspicion for this complication. Patients with sickle cell disease may also develop pulmonary artery hypertension.⁴⁴⁰ Unfortunately, echocardiogram has a poor specificity for identifying this subset of patients.⁴⁴⁰

Finally, in this era of injection drug use, noninfectious vasculitic-thrombotic complications are being seen with increasing frequency. Particulate and irritant drug carriers (e.g., talc [see eFig. 71-16], and cellulose [see eFig. 71-17]), and occasionally, the drugs themselves, may cause vascular inflammation and secondary thrombosis.⁴⁴¹ More commonly, uptake of the talc into the pulmonary interstitium results in fibrosis and advanced emphysema.⁴⁴²⁻⁴⁴⁴

Chest CT pulmonary angiographic findings of chronic thromboembolic disease. **A**, Recanalized arterial lumen, showing peripheral hypoattenuating material (*arrows*); **B**, Eccentric low-attenuation material along the wall of the affected vessel (*arrow*); **C**, Intra-vascular web (*arrowhead*); **D**, Inhomogeneous lung opacity representing areas of oligemia (the areas of decreased attenuation); **E**, Bronchial artery collateral vessels (*arrowheads*); **F**, Main pulmonary artery (MPA) enlargement, consistent with pulmonary hypertension; and **G**, Enlargement of the right atrium (RA) and right ventricle (RV), consistent with pulmonary hypertension. Note straightening of the interventricular septum, also consistent with elevated right heart pressures. (Courtesy Michael Gotway, MD.)

eFigure 57-13 Pulmonary artery air embolism. **A**, Frontal and **B**, lateral chest radiography performed for acute-onset chest pain following manipulation of a central venous catheter shows a gas and fluid level (*arrowheads*) in the main pulmonary artery. This finding resolved without sequelae. (Courtesy Michael Gotway, MD.)

Figure 57-14 Septic embolization. **A**, Frontal chest radiography performed in an intravenous drug user with fever shows multiple, bilateral, poorly defined nodular opacities (*arrows*), one of which is cavitory (*arrowhead*). **B**, Frontal chest radiography performed 2 years earlier, for comparison, appears normal. **C**, Frontal chest radiography performed one day following (**A**) shows progression in size of the nodular opacities (*arrows*). **D-G**, Axial-enhanced chest CT confirms the presence of multiple, bilateral, peripherally distributed nodules (*arrows*), many of which are cavitory (*arrowheads*). (Courtesy Michael Gotway, MD.)

eFigure 57-15 Methyl methacrylate pulmonary emboli following vertebroplasty. Oblique frontal image of the chest shows thoracic spine vertebroplasty material (*arrows*) with small foci of methyl methacrylate emboli in the right upper lobe (*arrowheads*). (Courtesy Michael Gotway, MD.)

eFigure 57-16 Methyl methacrylate pulmonary emboli following vertebroplasty. **A**, Frontal chest radiograph shows thoracic spine vertebroplasty material (*arrows*) with a small curvilinear focus of methyl methacrylate in the right interlobar pulmonary artery (*arrowhead*). **B** and **C**, Axial unenhanced chest CT confirms high attenuation in the right interlobar pulmonary artery (*arrows*), representing a methyl methacrylate embolism. Methyl methacrylate is also present in the azygos vein (*arrowheads*). (Courtesy Michael Gotway, MD.)

INTRODUCTION

Pulmonary hypertension manifests as an idiopathic form and as a complication of other circulatory conditions related to increases in pulmonary vascular resistance, increases in pulmonary arterial blood flow, and/or elevated left heart filling pressures. Five major pulmonary hypertension categories are recognized and organized into *World Health Organization* (WHO) groups based on similarities in clinical features and pathophysiologic and histologic findings (Table 58-1). One of these categories, pulmonary hypertension due to lung diseases and/or hypoxemia (group 3) is discussed in detail in Chapter 59 and chronic thromboembolic pulmonary hypertension (group 4) is discussed in detail in Chapter 57. This chapter focuses particularly on *pulmonary arterial hypertension* (PAH) and other conditions in group 1; it is primarily this group for which disease-specific therapies exist.

Pulmonary hypertension in general is not uncommon; it is diagnosed in more than 2% of all patients discharged from U.S. hospitals and in up to 9% of echocardiograms performed in a community setting.^{1,2} The majority of pulmonary hypertension diagnoses relate to left heart disease or lung disease, with only a small fraction accounted for by PAH (group 1) and chronic thromboembolic pulmonary hypertension (group 4). Idiopathic PAH in particular is rare, with an estimated incidence of approximately 1 case per million and a prevalence of 7 cases per million.^{3,4} Because current disease-specific pulmonary hypertension medications are approved only for idiopathic PAH and other WHO group 1 conditions, as listed in Table 58-1, it is critical for treating physicians to have a thorough understanding of the differential diagnosis and workup that is required for patients with suspected pulmonary hypertension.

EPIDEMIOLOGY

What is now called idiopathic PAH was first described at autopsy by Romberg in 1891.⁵ Patients with pulmonary hypertension of unknown cause were reported infrequently over the next 60 years,⁶ but began to be recognized more commonly after the advent of cardiac catheterization in the 1940s.^{7,8}

Idiopathic PAH was initially described as a disease of young women. The National Institutes of Health registry, conducted from 1981 to 1988, reported a mean age of 36 ± 15 years with a female-to-male ratio of 1.7:1,⁹ and other registries—including the more recent REVEAL registry—have reported even higher ratios of female to male patients.^{4,10,11} However, patients of both genders and of all ages are affected, and older patients are now recognized more frequently, with a mean age of approximately 50 years reported in registries from both the United States and Europe.^{10,11}

Patients older than 65 years with idiopathic PAH are also being recognized with greater frequency in the current era than in the past.^{12,13} Although most of these patients have pulmonary hypertension secondary to left heart disease or lung disease, idiopathic PAH does present in this age group. Patients with idiopathic PAH in the older age range have a more balanced gender ratio (female-to-male 1.2:1), greater abnormalities in baseline functional class and 6-minute walk distance (6MWD), and a worse prognosis, despite having a lower pulmonary vascular resistance at diagnosis (average 8.3 Wood units vs. 12 Wood units in younger patients).¹²

PATHOLOGY

Wood, in 1958,¹⁴ divided pulmonary hypertension into six types: (1) *passive*, as seen with increased pulmonary venous pressure due to raised left atrial or ventricular pressure; (2) *hyperkinetic*, caused by increased pulmonary blood flow; (3) *obstructive*, resulting from pulmonary embolism or thrombosis; (4) *obliterative*, manifested by a reduction of pulmonary vascular capacity; (5) *vasoconstrictive*, brought about by functional and presumably reversible vasospasm; and (6) *polygenic*, arising in two or more of the preceding ways. Vasoconstrictive pulmonary hypertension was noted most reliably in association with acute alveolar hypoxia, but was also seen as an added component in some patients with other forms of pulmonary hypertension. Wood¹⁴ also hypothesized that widespread “obliterative” pulmonary vascular disease potentially might complicate virtually all varieties of long-standing, severe pulmonary hypertension. Because multiple mechanisms are now known to be

common in severe pulmonary hypertension, regardless of underlying etiology, the modern classification has moved toward a more disease-focused classification. Nevertheless, these six pathophysiologic mechanisms remain relevant to modern understanding of the disease.

Also in 1958, Heath and Edwards¹⁵ documented the pathology of hypertensive pulmonary vascular disease in a study of 67 patients with congenital heart disease and 2 patients with idiopathic PAH, focusing on the muscular pulmonary arteries 100 to 1000 μ m in size. These investiga-

Figure 58-1 Typical advanced pulmonary arteriopathy in idiopathic pulmonary arterial hypertension. Note the proliferative changes in all three vessel layers, including intimal hyperplasia (I), medial hypertrophy (M), and adventitial fibrosis (A).

tors argued that the progression of lesions in these patients was so stereotyped as to allow division of the structural effects of pulmonary hypertension into six grades as follows: grade 1, medial hypertrophy of the pulmonary arteries and arterioles without intimal changes; grade 2, medial hypertrophy with cellular intimal proliferation; grade 3, medial hypertrophy, intimal proliferation, and intimal fibrosis; grade 4, progressive generalized vascular dilation and occlusion by intimal fibrosis and fibroelastosis; grade 5, appearance of dilation lesions, including veinlike branches of occluded pulmonary arteries, plexiform lesions, angiomatoid lesions, and cavernous lesions; and grade 6, necrotizing arteritis.

Heath and Edwards¹⁵ lumped the pathology of PAH associated with congenital heart disease and idiopathic PAH together, and large series of patients with the latter disorder were not available until 1970. In that year, Wagenvoort and Wagenvoort¹⁶ described the morphology of the pulmonary vessels of 150 persons in whom a diagnosis of unexplained PAH had been made. The largest subset ($N = 110$, 73%) had a histology consistent with what is now termed idiopathic PAH, and the pathologic abnormalities were strikingly similar to those described earlier by Heath and Edwards¹⁵ and Wood.¹⁴ The earliest abnormalities were medial hypertrophy of the muscular pulmonary arteries and muscularization of the arterioles, apparent in both children and adults with the disease. Less marked in children but apparent in all adults studied were intimal proliferation and laminar intimal fibrosis that gave an onionskin appearance to the pulmonary arteries, and plexiform lesions were found in 70%.¹⁶ A typical arteriopathic muscular artery is shown in **Figure 58-1**.

A pathologic pattern consistent with chronic pulmonary thromboembolism was also seen in some of the patients with unexplained pulmonary hypertension in this series, present in 31 patients (21%). Half were noted in retrospect to have had other evidence of chronic thromboembolism, such as deep venous thrombosis. These patients had a combination of abnormalities including evidence of recent pulmonary thrombi, thrombi in the process of reorganization, and older organized fibrosis, appearing as intimal fibrosis, and lacked onion skin lesions, plexiform and other

dilation lesions. Notably, this chronic thromboembolic pattern is rarely seen in patients diagnosed as idiopathic PAH in modern series, likely due to universal screening for chronic thromboembolic disease.¹⁷ These earlier histopathologic studies were, no doubt, limited by incomplete or erroneous phenotyping, in that the appropriate workup of pulmonary hypertension patients has only been clarified in the “recent” era, that is, when approved therapies became available.

Pulmonary veno-occlusive disease (PVOD) is a rare form of PAH that has virtually identical hemodynamic findings and in many cases similar clinical findings as in idiopathic PAH. It was seen in 3% of the pathology specimens in the series by Wagenvoort and Wagenvoort, and continues to be difficult, in many cases, to distinguish from idiopathic PAH using clinical means. The characteristic histologic feature of PVOD is obstruction of pulmonary venules and veins by loose, fibrous remodeling of the intima that may totally occlude the lumen; in addition arterial changes are usually evident.¹⁷⁻¹⁹

Despite the distinct pathologic findings in idiopathic PAH, some degree of vascular remodeling takes place with essentially all forms of pulmonary hypertension,²⁰⁻²² and even severe arteriopathic changes are, in fact, not unique to idiopathic PAH, having been reported in other forms of PAH (group 1)^{23,24} and in chronic thromboembolic pulmonary hypertension.²⁵ For this reason, in addition to the risk of lung biopsy in patients with pulmonary hypertension, one rarely obtains pathologic tissue before lung transplantation or death. Similarly, lung biopsy in pulmonary hypertension due to congenital heart disease with left-to-right shunting is also no longer common.

PATHOGENESIS AND ETIOLOGY

A dramatic change has taken place over the past several years in our thinking regarding the pathogenesis of idiopathic PAH. The “paradigm” has shifted from one of vasoconstriction to one of growth and proliferation. There are several lines of evidence suggesting that idiopathic PAH develops as a result of abnormal proliferation of vascular smooth muscle cells affecting all three layers of the vessel wall and leading to intimal hyperplasia, medial hypertrophy, and adventitial proliferation. What initiates this abnormal growth is not entirely known, but there are several clues. The concept of genetic predisposition toward growth and proliferation has more recently emerged. Mutations in the *bone morphogenic protein receptor 2 (BMPR2)* gene have been reported in patients with the familial form of idiopathic PAH.²⁶ This gene contributes to the apoptotic process through a complex series of messenger proteins, as part of the *transforming growth factor-β* family of genes.

Accordingly, the possibility emerges that pulmonary arteriopathy is a failure of normal apoptosis. Some investigators have even referred to idiopathic PAH as “cancer of the pulmonary artery.” Although this is an attractive hypothesis, the story is not that simple. For one, the presence of a *BMPR2* mutation is not always associated with the development of idiopathic PAH. It is likely that another genetic or acquired insult is required to initiate the arteriopathic process. Defects in a specific voltage-gated

potassium ion channel, the *Kv1.5* channel, have been found in the pulmonary artery smooth muscle cells from patients with idiopathic PAH.²⁶ A defect or deficiency of this channel allows excess calcium to enter the cell and thus promotes both cell contraction and growth. Overexpression of the serotonin transporter has been described in patients with idiopathic PAH.²⁷ This genetic defect might lead to increased internalization of serotonin and subsequent smooth muscle cell growth. Recent interest has focused on the role of impaired apoptosis on the development of proliferative arteriopathy in idiopathic PAH. It is clear that functional mutations seen in the *BMPR2* gene with resultant abnormal downstream signaling results in impaired apoptosis.²⁸⁻³⁰

In addition to potential genetic defects, several abnormalities in endothelial cell function have been found, many of which are likely a result of some vascular insult. The basis for currently approved therapeutics is the deficiency in prostacyclin and nitric oxide release and the excess in endothelin-1 and its receptor expression in patients with pulmonary hypertension.³¹⁻³⁴ Some of the complex cellular and molecular processes contributing to idiopathic PAH are shown in Figure 58-2.

OTHER GROUP 1 CONDITIONS

PULMONARY VENO-OCCLUSIVE DISEASE

Veno-occlusive disease has been associated with viral syndromes, toxin exposure, and chemotherapy, but may also be seen in an idiopathic form.¹⁹ Unlike idiopathic PAH, the male-to-female ratio in adults with PVOD is close to 1:1. A familial form of veno-occlusive disease also has been noted, including a subset of patients who carry the *BMPR2* mutation.¹⁹ Differentiation from idiopathic PAH can be difficult. Suggestive findings include more hypoxia, a lower *DL_{CO}* on pulmonary function testing, and prominent interlobular septal thickening (Kerley B) lines on chest radiographs in the absence of other signs of left-sided heart failure (Fig. 58-3A). *Computed tomography (CT)* scanning may reveal interlobular septal thickening (see Fig. 58-3B), pleural effusions, and enlarged pulmonary arteries. The perfusion lung scan may show defects suggestive of thromboembolism but with unremarkable pulmonary angiograms.³⁵ In addition, patients with PVOD may develop acute pulmonary edema in response to pharmacologic agents that reduce upstream *pulmonary vascular resistance (PVR)* and increase cardiac output, such as prostacyclin. This phenomenon probably is caused by an increase in pulmonary blood volume in the face of downstream vascular obstruction. A recent analysis of PVOD cases suggested that *bronchoalveolar lavage (BAL)* could be useful, because patients with PVOD almost always had increased hemosiderin-laden macrophages in BAL fluid.³⁶

PULMONARY ARTERIAL HYPERTENSION ASSOCIATED WITH OTHER CONDITIONS

Several systemic diseases or exposures have been shown, epidemiologically, to be associated with PAH (see Table 58-1). For example, approximately 8% of patients with the

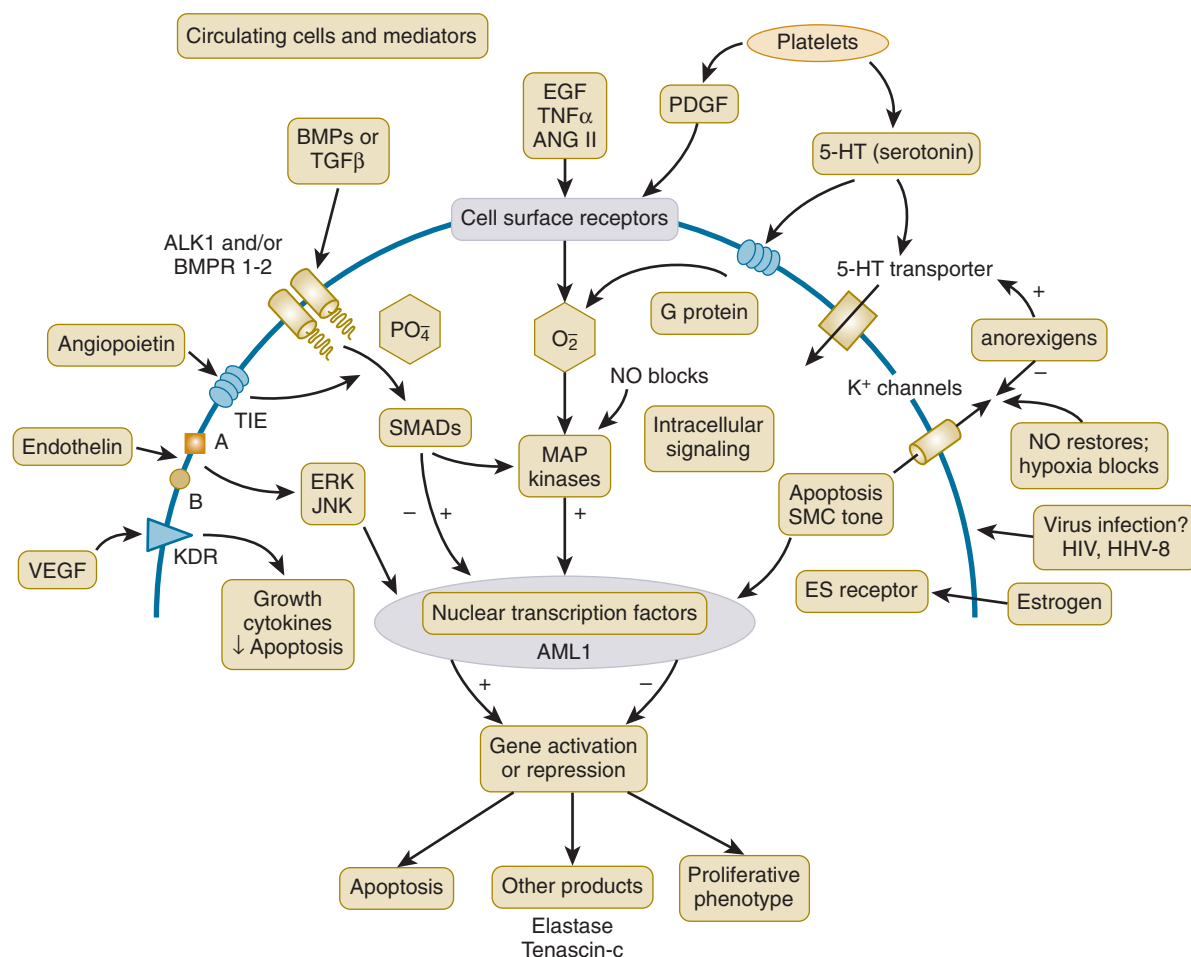

Figure 58-2 Schematic of the possible pathogenetic factors in idiopathic pulmonary arterial hypertension. A, endothelin A receptor; ALK, activin receptor kinase-like; AML1, acute myeloid leukemia 1; Ang II, angiotensin II; B, endothelin B receptor; BMP, bone morphogenetic protein; BMPR1-2, bone morphogenetic protein 1-2; EGF, epidermal growth factor; ERK, extracellular signal-regulated kinases; 5-HT, serotonin; HHV-8, human herpes virus 8; HIV, human immunodeficiency virus; JNK, c-Jun amino-terminal kinases; KDR, kinase insert domain receptor; MAP, mitogen activated protein; NO, nitric oxide; PDGF, platelet derived growth factor; SMADs, Sma and Mad related proteins; TGF β , transforming growth factor beta; TIE, tyrosine kinase with immunoglobulin-line and EGF-like domains; TNF α , tumor necrosis factor alpha; VEGF, vascular endothelial growth factor.

scleroderma spectrum of diseases, most notably limited scleroderma (previously CREST, or calcinosis cutis, Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia) have been reported to have PAH (eFig. 58-1) confirmed by right heart catheterization,³⁷ and even higher rates have been seen in some echocardiography series.³⁸ Pulmonary vascular involvement is associated with worse survival in scleroderma.³⁹ Other connective tissue diseases associated with PAH, albeit less commonly, include systemic lupus erythematosus, mixed connective tissue disease, and rheumatoid arthritis.⁴⁰

Congenital heart disease is a well-recognized “risk factor” for development of PAH. In 1958, Wood¹⁴ coined the term “Eisenmenger’s complex” to describe pulmonary hypertension due to high PVR, with reversed (i.e., right-to-left) shunting through a large ventricular septal defect. Subsequently, the term has been used to describe pulmonary hypertension with cyanosis coupled with any systemic-to-pulmonary circulatory shunt. The likelihood of developing pulmonary hypertension depends on the size of the defect. However, patients with even small atrial septal defects can develop pulmonary hypertension. These patients may, in

fact, have idiopathic PAH and the atrial septal defect merely serves as a “trigger” in a susceptible patient.

In patients with ventricular septal defects, it has been shown that only 3% of patients with a defect of 1.5 cm or smaller develop Eisenmenger syndrome, whereas 50% of patients with a large defect develop significant pulmonary hypertension, which also appears earlier than in atrial septal defect (eFig. 58-2), often in infancy.⁴¹ PAH due to true Eisenmenger syndrome is associated with a longer natural history and more preserved right ventricular compensation and, hence, longer periods of clinical stability. The defect itself may also provide a protective mechanism, providing a route for blood to reach the underfilled left ventricle. However, right heart failure does eventually develop in many patients, and just as in idiopathic PAH, an elevated right atrial pressure and low cardiac output carry a poor prognosis.⁴²

The effects of drugs and toxins on the human pulmonary circulation have been graphically demonstrated in the past. Between 1967 and 1970 in Switzerland, Austria, and Germany, a 20-fold increase in pulmonary hypertension was observed after the introduction of aminorex, an

Figure 58-3 Pulmonary veno-occlusive disease. **A**, Frontal chest radiograph shows central pulmonary arterial enlargement, consistent with pulmonary hypertension. Central increased opacity is noted, with a background of linear opacities, some of which are consistent with interlobular septal thickening (also called Kerley B lines, *arrowheads*). **B**, Axial chest CT displayed in lung windows shows patchy areas of inhomogeneous lung opacity, with some areas of increased attenuation consistent with ground-glass opacity, best seen in the medial lung bases. Faint peripheral linear opacity and interlobular septal thickening (*arrows*) is present. The patient eventually was treated with bilateral lung transplantation. (Courtesy Michael Gotway, MD.)

appetite suppressant resembling epinephrine and amphetamine.⁴³ The pulmonary lesions produced by this agent resembled plexogenic pulmonary arteriopathy in every respect. Pulmonary hypertension has also been associated with the appetite suppressants fenfluramine (eFig. 58-3) and dexfenfluramine.⁴⁴ In a case-controlled prospective study performed in Europe, the risk of developing pulmonary hypertension was increased by 20-fold in individuals who used one of these drugs for periods exceeding 3 months. Stimulants have also been suspected of causing pulmonary hypertension, based on both mechanistic similarities with the anorexigens and case reports, case series, and a single-center case-control study.^{45,46} In the latter study, an especially strong association between methamphetamine use and PAH was identified, with patients with PAH and no other identifiable risk factors 10 times more likely to have

used methamphetamine than a matched control group of patients with other forms of PAH.⁴⁷ Other medications suspected of causing pulmonary hypertension include chemotherapeutic agents, mainly in association with PVOD,⁴⁸ and dasatinib, a tyrosine kinase inhibitor whose use in the treatment of chronic myelogenous leukemia has been associated with the development of PAH.⁴⁹

Portal hypertension is another disease associated with PAH (eFig. 58-4) and is discussed further in Chapter 93. Mantz and Craig⁵⁰ first described simultaneous presentation of portal and pulmonary hypertension in a patient with portal vein thrombosis, speculating, as would others in the years following,⁵¹ that multiple emboli emanating from portacaval anastomoses were responsible for the pulmonary hypertension. Subsequent hypotheses have suggested a vasoactive mediator-based mechanism related to porto-systemic shunting, whereby vasoactive substances, normally cleared in the liver, reach the pulmonary vasculature, while yet another hypothesis has focused on derangements in genes related to estrogen signaling.⁵² Portopulmonary hypertension is similar to other types of PAH histologically and is characterized hemodynamically by elevations in pulmonary arterial pressure and pulmonary vascular resistance. Incidence is estimated at 0.73% of all patients with portal hypertension, based on a large autopsy study,⁵³ and rates of up to 4% to 5% have been reported in end-stage patients undergoing workup for liver transplantation.^{54,55}

In end-stage liver disease, hemodynamic assessment is frequently complicated by the presence of a high cardiac output related to splanchnic vasodilation and by the presence of volume overload and/or diastolic heart failure.⁵⁵ As a result, portopulmonary hypertension patients tend to have higher cardiac outputs and lower PVRs compared with other WHO group 1 PAH patients.⁵⁶ Despite more favorable hemodynamics, the mortality risk following liver transplantation has been shown to be approximately 50% in patients with even mild to moderate pulmonary hypertension (defined as a PVR >3.1 Wood units in this series), particularly when undiagnosed until the time of transplantation.⁵⁷ Knowledge regarding the high mortality in patients with portopulmonary hypertension undergoing orthotopic liver transplantation has led to development of aggressive strategies for screening and treatment of these patients before transplantation; recommendations include echocardiography in all patients, right heart catheterization for patients whose estimated right ventricular systolic pressure exceeds 50 mm Hg, vasodilator treatment of patients whose pulmonary hypertension is due to PAH, and liver transplantation of these patients only when treatment is successful in lowering the mean PAH to less than approximately 35 mm Hg.^{55,58}

The association between *human immunodeficiency virus* (HIV) and PAH is well known. In several studies, the incidence of pulmonary hypertension in HIV has been reported as high as 0.5%.^{59,60} The mechanism of HIV-associated pulmonary hypertension is not known, although theories include release of cytokines and growth factors and the presence of human herpesvirus 8, a promoter of angiogenesis as seen in Kaposi sarcoma. One report noted the presence of human herpesvirus 8 in the cells from plexiform lesions in 10 of 16 patients with idiopathic PAH.⁶¹ Subsequent reports, however, failed to reveal human herpesvirus

8 in plexiform lesions.^{62,63} Pulmonary hypertension can develop in all stages of HIV, including in patients with no detectable viral load. A concomitant history of illicit intravenous drug use is noted in as many as 42% of cases,⁶⁴ and at the authors' Pulmonary Hypertension Center, the vast majority of patients with HIV-associated PAH have a methamphetamine use history, suggesting the possibility that illicit drugs contribute substantially to the risk of PAH in HIV patients. Clinical and hemodynamic features of HIV-associated pulmonary hypertension are similar to those of idiopathic PAH (eFig. 58-5), although increased mortality is associated both with measures of HIV severity (high viral load, low CD4 count) and with typical PAH prognostic markers, such as worse functional class, low cardiac index, and history of right heart failure.⁶⁵

SYMPTOMS

Dyspnea is the cardinal symptom of idiopathic PAH, described by more than 95% of patients in major clinical series,⁹ usually noted first on exertion and gradually with less and less activity. Closely related to dyspnea are sensations of fatigue and weakness, reported by a majority of patients with idiopathic PAH.⁹ These sensations usually are experienced before the general disability that is present with advanced disease, and presumably reflect impaired tissue oxygenation resulting from inadequate cardiac output.

Substernal chest pain is also commonly reported in patients with idiopathic PAH,⁶⁶ and frequently arises on exertion, radiating to the left shoulder or axilla, and relieved by rest. Similarities with angina pectoris have led to the suggestion that the pain may relate to coronary insufficiency in the presence of increased right ventricular work and hypoxemia. However, pain may be present in young patients without coronary artery disease, and alternative mechanisms that have been considered include subendocardial ischemia related to demand-perfusion mismatch,⁶⁷ ischemia related to direct compression of the left main coronary artery by the enlarged pulmonary trunk,⁶⁸ and nonischemic pain caused directly by the distention of the pulmonary artery, whose afferents enter the nervous system along the same pathways as afferents from the heart.⁶⁹ In addition to chest pain, hoarseness may result if the enlarged main pulmonary artery compresses the recurrent laryngeal nerve.

Syncope, usually with exertion, occurs in some patients with idiopathic PAH and may be its initial manifestation. Syncope is probably caused by a decrease in cerebral blood flow that follows an increase in pulmonary artery pressure and a decrease in cardiac output, and it is associated with a poor prognosis. Late findings in PAH include peripheral edema and ascites related to decompensated right ventricular failure, and hemoptysis. For the latter, bronchial artery embolization is often successful, but mortality following an initial episode of hemoptysis is high.⁷⁰

PHYSICAL FINDINGS

Patients with early idiopathic PAH may manifest no obvious physical abnormality. However, signs of pulmonary hyper-

tension and right ventricular failure should be evident with advanced disease. As Wood¹⁴ observed, the hands and feet of a patient with severe pulmonary hypertension are cold, the peripheral pulse is diminished, the blood pressure is likely to be low, and the pulse pressure is reduced. Signs of systemic venous hypertension are often present, including a prominent jugular venous *a* wave, which is exaggerated by abdominal compression (hepatojugular reflux) and transmitted to the liver in a presystolic hepatic pulse, and prominent *c-v* waves, which are indicative of tricuspid regurgitation. Palpation of the chest may reveal a right ventricular lift at the left sternal border that is sustained throughout the pressure-overloaded cardiac contraction, in contrast to the unsustained parasternal impulse felt in pure volume overload.

On auscultation of the chest, the second heart sound is closely split, and the second (pulmonic) component is accentuated. The valvular closure sound should increase in intensity on inspiration and may become palpable as pulmonary artery pressure rises. A systolic ejection click reflecting sudden distention of the right ventricular wall also may be heard. A murmur of tricuspid regurgitation heard best along the left sternal border and increasing in intensity with inspiration, is frequent. A pulmonic regurgitant murmur may become evident after dilation of the main pulmonary artery and its valvular annulus. Diastolic vibration of the aortic valve leaflet (Graham Steell murmur) may be present along with third and fourth heart sounds. In addition to these findings, patients with right-sided heart failure usually have peripheral edema and abdominal distention due to ascites. If tricuspid regurgitation is present, the liver may become pulsatile.

Cyanosis is seen with variable frequency in patients with idiopathic PAH and is likely to be a late phenomenon. It is most marked during exercise but also may be present at rest. Peripheral vasoconstriction and impaired oxygenation of arterial blood due to mixed venous hypoxemia resulting from the decreased cardiac output appear to be the most common mechanisms. Patients in whom right atrial pressure equals or exceeds left atrial pressure may develop severe hypoxemia and cyanosis because of opening of the foramen ovale with subsequent right-to-left shunting of blood. In addition to cyanosis, vascular plethora may be observed in hypoxemic patients with secondary polycythemia. Clubbing is not a usual manifestation of idiopathic PAH. The presence of clubbing warrants a careful search for other causes of pulmonary vascular disease such as congenital heart disease, liver disease, PVOD, or idiopathic pulmonary fibrosis.

DIAGNOSIS

A thorough workup is required in all patients in whom PAH (WHO group 1) is suspected. A diagnostic algorithm has been developed, including basic tests—that should be completed in all patients—and optional tests that are performed when indicated (Fig. 58-4). A similarly thorough workup will be required in many patients felt to have pulmonary hypertension related to a WHO group 2 or 3 condition, but a more limited evaluation may be appropriate in a subset of patients with advanced left heart or lung disease, borderline

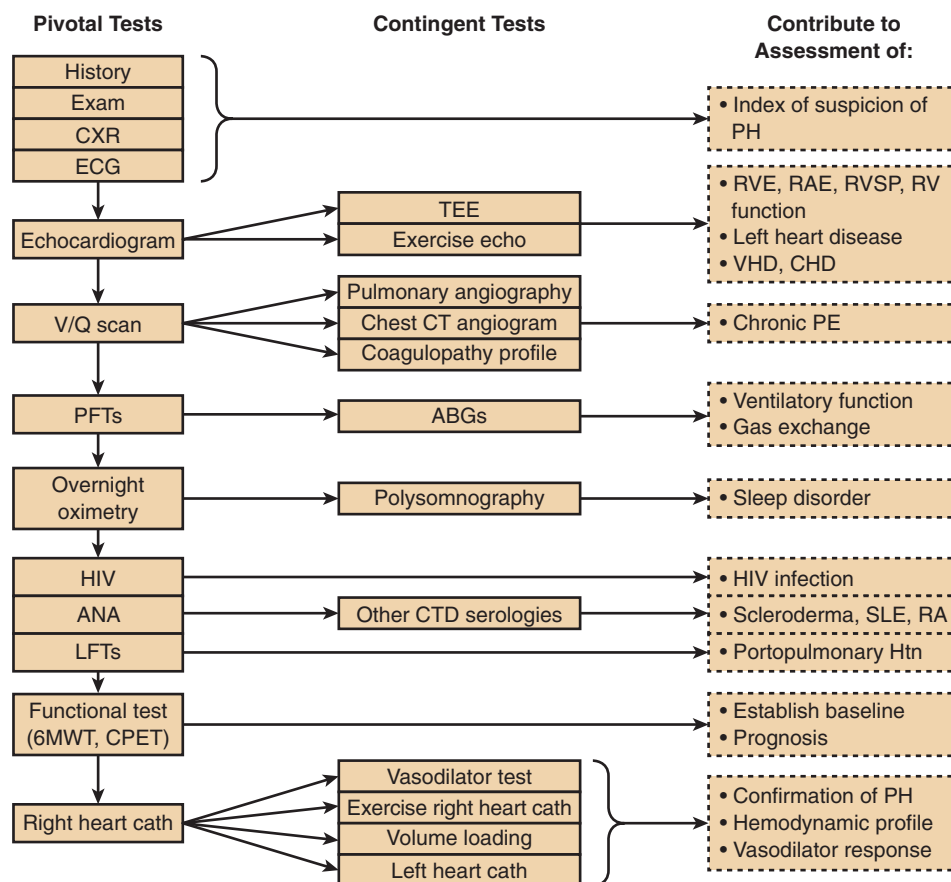

Figure 58-4 Diagnostic approach to pulmonary arterial hypertension. Pivotal tests are required for a definitive diagnosis of idiopathic pulmonary arterial hypertension, while contingent tests are performed when clinically indicated. ABGs, arterial blood gas; ANA, antinuclear antibody; CHD, congenital heart disease; CPET, cardiopulmonary exercise test; CTD, connective tissue disease; CXR, chest xray; ECG, electrocardiogram; HIV, human immunodeficiency virus; HTN, hypertension; LFTs, liver function tests; PE, pulmonary embolism; RA, rheumatoid arthritis; RAE, right atrial enlargement; RV, right ventricle; RVE, right ventricular enlargement; RVSP, right ventricular systolic pressure; 6MWT, six minute walk test; SLE, systemic lupus erythematosus; TEE, transesophageal echocardiogram; V/Q, ventilation perfusion scan; VHD, valvular heart disease. (From McLaughlin VV, Archer SL, Badesch DB, et al: ACCF/AHA 2009 expert consensus document on pulmonary hypertension: a report of the American College of Cardiology Foundation Task Force on Expert Consensus Documents and the American Heart Association: developed in collaboration with the American College of Chest Physicians, American Thoracic Society, Inc., and the Pulmonary Hypertension Association. *Circulation* 119:2250–2294, 2009.)

or mild pulmonary hypertension based on echocardiogram (right ventricular systolic pressure <50 mm Hg, no right ventricular dysfunction), and plans to focus therapy on the underlying disease process (i.e., no PAH-specific therapies).

The initial history should include a thorough review of symptoms as well as any potential pulmonary hypertension risk factors, including connective tissue disease, congenital heart disease, liver disease, obstructive sleep apnea, prior pulmonary embolism, and prior diet pill or stimulant use. Family history should be reviewed, including any family members with pulmonary hypertension, pulmonary embolism, or hereditary hemorrhagic telangiectasia. On physical examination, in addition to the potential physical findings described, particular attention should also be paid to findings that would suggest a non-idiopathic PAH diagnosis, such as significant crackles or wheezing on pulmonary examination, skin changes suggestive of connective tissue disease, pulmonary flow murmurs (suggestive of chronic thromboembolic disease), or evidence of clubbing.

Chest radiography is useful for suggesting the presence of pulmonary hypertension and in providing clues of underlying conditions such as parenchymal lung disease. In patients with idiopathic PAH, the radiograph characteristi-

cally reveals enlargement of the main pulmonary artery, increased width of the descending branch of the right pulmonary artery, peripheral oligemia, and an enlarged heart (Fig. 58-5 and eFig. 58-6). The axial CT scan can confirm the increased diameter of the main pulmonary artery (see Fig. 58-5).

The electrocardiogram usually discloses right ventricular hypertrophy in patients with advanced idiopathic PAH. Electrocardiographic criteria for right ventricular hypertrophy include a QRS axis in the frontal plane that is greater than or equal to 110 degrees, an R wave in lead V1 that is greater than 5 mm, an R-to-S ratio in V1 that is greater than 1, and an R-to-S ratio in lead V6 that is less than 1. Patients also may manifest right atrial enlargement with a symmetrical and peaked P wave in lead II that is greater than 2.5 mm in amplitude. ST segment depression and T-wave inversion may be seen in the anterior chest leads. These abnormalities may not be present if pulmonary hypertension is not pronounced or if patients are young.

Systemic arterial blood gas analysis in patients with idiopathic PAH usually reveals a low arterial carbon dioxide pressure (arterial PCO_2) and a normal pH, reflecting chronic respiratory alkalosis. The systemic arterial oxygen pressure

Figure 58-5 Idiopathic pulmonary arterial hypertension: chest radiographic and chest CT findings. Frontal (A) and lateral (B) chest radiographs show bilateral, symmetrical central pulmonary arterial enlargement. The lateral radiograph (B) reveals “filling” of the substernal regions (the “retrosternal clear space”), representing enlargement of the right ventricular outflow tract (arrow). C, Axial enhanced chest CT shows enlargement of the main pulmonary artery, consistent with elevated pulmonary arterial pressure. The main pulmonary artery (MPA) is measured as indicated, typically at the widest portion of the vessel at or near the level of the bifurcation: ≥ 29 mm in transverse diameter is considered abnormal. Alternatively, the size of the main pulmonary artery may be compared with the ascending aorta (a) at the same level. Assuming the aorta is not pathologically enlarged, the main pulmonary artery may be considered abnormally enlarged if its diameter, typically measured at the main pulmonary artery bifurcation, exceeds the ascending aortic diameter at the same level, as is seen in this case. (Courtesy Michael Gotway, MD.)

(arterial PO_2) may be normal or abnormal, but the alveolar-to-arterial PO_2 difference usually is increased. Several mechanisms have been proposed for the hypoxemia of patients with idiopathic PAH, including diffusion impairment caused by a reduction in the number of pulmonary vessels coupled with the shortened time spent by erythrocytes in traversing the pulmonary circulation; ventilation-perfusion mismatching due to alterations in pulmonary blood flow; and concomitant conditions such as bronchospasm, right-to-left intracardiac shunting through a patent foramen ovale, and a reduced mixed venous PO_2 resulting from a low cardiac output.⁷¹ Blood studies are another important part of the laboratory evaluation. The complete blood count is particularly helpful in documenting polycythemia, which is present in hypoxemic patients with PAH or pulmonary hypertension related to lung disease.

Ventilation-perfusion lung scanning has been used primarily to differentiate idiopathic PAH from chronic pulmonary thromboembolism. Worsley and associates studied 75 patients with pulmonary hypertension of various types and found that 24 of 25 (96%) patients with chronic thromboembolic pulmonary hypertension had high probability scans, while one patient had an intermediate probability scan.⁷² In contrast, 33 of 35 patients (94%) with idiopathic PAH had a low probability scan (eFig. 58-7), one had an intermediate probability scan, and one had a high probability scan. Based on these and other studies,⁷³ patients with otherwise unexplained PAH who have an intermediate or high probability V/Q scan should undergo further evaluation, including pulmonary angiography. CT scanning is not recommended for evaluating chronic pulmonary embolism, because the sensitivity has been lower than V/Q scanning in head-to-head studies.⁷⁴

Pulmonary function tests performed in patients with idiopathic PAH usually reveal normal expiratory flow rates with normal or mildly reduced lung volumes. The modest restrictive defect has been attributed to diminished disten-

sibility of the pulmonary vessels.⁷⁵ The DL_{CO} is often reduced to a mild or moderate degree,⁹ and a low DL_{CO} out of proportion to lung volumes has been used in screening algorithms to identify scleroderma patients who are at increased risk of having pulmonary hypertension.⁷⁶

Exercise testing may serve to unmask physiologic abnormalities in patients with idiopathic PAH if these abnormalities are not present at rest. Characteristically, patients with PAH achieve their target heart rate and anaerobic threshold at low levels of exercise, often accompanied by a reduction in the arterial PO_2 or an increase in the alveolar-to-arterial PO_2 difference. The dead space-to-tidal volume ratio either fails to decrease, as it should in healthy persons, or actually increases during graded exercise. Submaximal exercise testing measured by the 6MWD is extremely useful as a prognostic marker and in following patients on therapy; individuals whose walk distance is greater than 380 to 400 m have a better prognosis.⁷⁷ Additionally, patients with a postwalk test decline in heart rate of at least 16 beats/min have a better prognosis than those with a smaller decline, measured as heart rate at end of the test versus heart rate after 1 minute of recovery.⁷⁸ The 6MWD has served as the primary outcome end point in several pivotal pulmonary hypertension clinical trials.

ECHOCARDIOGRAM

The echocardiogram is a key diagnostic test in the evaluation of PAH, providing an assessment of right ventricular size and function, an estimate of the pulmonary arterial systolic pressure, and in ruling out other cardiac conditions such as mitral valve disease and left ventricular systolic or diastolic dysfunction. Current guidelines recommend using echocardiography to estimate the *likelihood* of pulmonary hypertension, based on the Doppler-derived peak *tricuspid jet velocity* (TR jet) and using the equation: right ventricular systolic pressure = $[(TR \text{ jet})^2 \times 4] + \text{estimated central venous}$

Figure 58-6 Echocardiogram in pulmonary hypertension. In addition to an elevated estimated pulmonary artery systolic pressure, the echocardiogram in pulmonary hypertension may show a variety of abnormalities including a dilated right atrium (RA) and right ventricle (RV), as seen on this image, shift of the interventricular septum, and a pericardial effusion. (See also [Video 58-1](#).) LA, left atrium; LV, left ventricle.

pressure. Specifically, a peak TR jet less than 2.8 m/sec is unlikely to represent PAH, whereas a velocity greater than 3.4 m/sec is consistent with probable pulmonary hypertension, and values between 2.8 and 3.4 m/sec, corresponding to estimated right ventricular systolic pressures of 37 to 50 mm Hg, are considered indeterminate.⁷⁹

Importantly, the accuracy and precision of this estimate compared with right heart catheterization measurement has been only moderate in many studies and, in certain circumstances, a decision to proceed with right heart catheterization may be appropriate even with a normal estimated pulmonary artery systolic pressure. It is also important to look for other echocardiographic findings suggestive of pulmonary hypertension. Suspicious findings include dilated right heart chambers, systolic flattening or diastolic bulging of the interventricular septum ([Fig. 58-6](#) and [Video 58-1](#)), and a short pulmonary arterial acceleration time, although in general these tend to be later findings.⁸⁰ Intracardiac shunting may be observed after the intravenous injection of contrast or microbubbles. Echocardiographic measurements may also be useful in estimating prognosis and tracking response to therapy. Importantly, this does not include estimated pulmonary arterial systolic pressure, which by itself does not have prognostic value in idiopathic PAH. Instead, echocardiographic measures suggesting right ventricular dysfunction should be sought, including dilated right heart chambers, reduced right ventricular systolic function, significant tricuspid regurgitation, marked septal shift with a small left ventricular chamber, and a pericardial effusion.⁸¹

CARDIAC CATHETERIZATION

In the evaluation of idiopathic PAH, right heart catheterization is mandatory to document the presence and severity of pulmonary hypertension, rule out cardiac causes, and determine whether there is acute pulmonary vasoreactivity using pharmacologic agents. Hemodynamic values, espe-

cially right atrial pressure and cardiac index, correlate closely with survival.^{82,83} Cardiac chamber and pulmonary arterial pressures are recorded, and the *pulmonary capillary wedge pressure* (PPW) is measured to rule out disease at the level of the left ventricle, left atrium, or large pulmonary veins. Cardiac output is measured, and the pulmonary and systemic vascular resistances are calculated. Blood gas samples are obtained to determine oxygen tensions and contents in the two circulations. Left-to-right intracardiac shunts may be excluded by the measurements of blood oxygen tensions and contents in the various cardiac chambers and by indicator techniques.

PAH—without left-sided heart involvement—is defined hemodynamically as a mean pulmonary arterial pressure greater than or equal to 25 mm Hg and a PPW less than 16 mm Hg. A PVR greater than or equal to 3 Wood units has been included in some but not other definitions, and the vast majority of patients with idiopathic PAH will easily meet this cutoff at diagnosis, with an average PVR at diagnosis of 12 Wood units or higher.^{10,84,85}

The measurement of PPW in pulmonary hypertension deserves extra attention, because a reading greater than 15 mm Hg suggests a diagnosis of left-sided heart disease rather than PAH. The PPW is obtained by transiently occluding blood flow in the pulmonary artery using an inflated, balloon-tipped catheter. The PPW can be inaccurate because of incomplete occlusion, resulting in a blunted pulmonary arterial pressure measurement rather than a true PPW, or because the catheter tip is not located centrally within the pulmonary artery. Inspecting the catheter location under fluoroscopy and ensuring that the resultant pressure tracings are consistent with a left atrial pressure waveform helps ensure an accurate reading. In some cases, a better waveform may be obtained by partially deflating the balloon and repositioning it. Additionally, a wedge position of the catheter can be confirmed by aspirating blood from the distal lumen and documenting high oxygen saturation indicative of pulmonary capillary blood. Because this measurement is so critical to the diagnosis, some centers routinely measure left ventricular end-diastolic pressures during all diagnostic right heart catheterizations.

Acute vasodilator testing is often performed during the initial catheterization. This study is performed using a short-acting agent, such as inhaled nitric oxide, adenosine, or prostacyclin. Oxygen and nitrates are not adequate testing agents in patients with idiopathic PAH. Criteria for defining vasoresponsiveness are discussed later, but basically, acute testing is performed to identify patients who will benefit from long-term vasodilator therapy.

TREATMENT AND PROGNOSIS

Idiopathic and other forms of PAH are now treatable diseases. Clear-cut short- and long-term benefits are seen with currently available therapies.⁸⁶ To optimize a patient's outcome, a comprehensive medical approach is essential. Once the diagnostic process in a patient with pulmonary hypertension is complete and the patient is characterized as having PAH (WHO group 1), therapy should be initiated. But many questions arise regarding PAH therapy. What are the goals and expected outcomes of treatment? Which drug

should be used first? When should another therapy be added? Should more than one therapy be used? In what order? When should transplantation be considered?

Therapy for PAH may be subdivided into “supportive” or “conventional” therapies, defined as empirical treatments or recommendations for which there is no prospective, randomized, controlled data, and “specific” or “targeted” therapies, which have been tested and approved by regulatory authorities for the treatment of PAH.

SUPPORTIVE THERAPIES

Exercise and Physical Activity

Although data are limited, consensus guidelines support the benefits of exercise in PAH patients. However, patients should avoid activities that lead to undue symptoms such as severe dyspnea, chest pain, light-headedness, or syncope. Two small studies ($N = 22$ and $N = 30$) have demonstrated that exercise and respiratory training can be safe and lead to measurable improvements in subjective and objective parameters.^{87,88} In these studies, patients undergoing 12- to 15-week courses of supervised aerobic exercise and resistance training were found to have significant improvement in 6MWD outcomes and peak oxygen consumption compared to controls. No significant safety concerns were identified, and there were no significant changes in echocardiographic measures of right heart function or in brain natriuretic peptide levels.

Avoidance of Altitude

Hypobaric hypoxia causes pulmonary vasoconstriction and, thus, can worsen pulmonary hypertension and lead to symptomatic worsening in PAH patients. It is generally recommended that patients flying on commercial airliners (pressurized to 1500 to 2400 m) or traveling to elevation above 5000 feet be evaluated for supplemental oxygen⁸⁹ (see Chapter 25). Not surprisingly, patients with severe PAH residing at high elevations may improve if they move to sea level.

Avoidance of Pregnancy

Pregnancy is extremely risky in patients with PAH, with a high peripartum mortality rate, especially after delivery.⁹⁰ Although there are case reports of patients managed with epoprostenol and undergoing successful pregnancies and deliveries,^{91,92} it is strongly recommended that women of childbearing potential use appropriate methods of birth control to avoid pregnancy. In terms of which birth control method is preferable, none of the highly effective methods are absolutely contraindicated in PAH, although surgical procedures (sterilization) may be too high risk for many patients. Additionally, some experts recommend avoiding estrogen-containing hormonal contraceptives, particularly in patients who are not anticoagulated. Efficacy can be generally thought of in three tiers: (1) sterilization, intrauterine devices, and progestin-containing implants; (2) combination and progestin-only birth control pills, the estrogen-containing transvaginal ring, and injectable progestins; and (3) barrier methods, such as the condom and diaphragm, with the latter choices considered appropriate in PAH only when used in combination with another method.⁹³

Anticoagulation

There is strong rationale for the use of anticoagulants in PAH. Many of the endothelial cell abnormalities that predispose patients to pulmonary arteriopathy also increase thrombosis. The presence of heart failure and an indwelling central venous catheter are independent risk factors for thromboembolic events, which are poorly tolerated by patients with an already marginal pulmonary vascular reserve. In addition, microscopic thrombotic lesions in the pulmonary vasculature are well documented in PAH patients.

Warfarin. Warfarin is the anticoagulant most frequently used in patients with PAH. In PAH clinical trial registries, about 50% to 85% of patients are on anticoagulants at study entry.⁹⁴ However, anticoagulation has risks (i.e., bleeding) as well as the need for frequent monitoring. To justify the use of warfarin in PAH, nine studies have examined the effects of warfarin in idiopathic PAH. All were retrospective analyses with some patients on warfarin and others untreated.^{95,96,96a} Although better survival was documented in patients on warfarin compared with those not anticoagulated in six of nine studies, including the study by Rich and coworkers,¹¹⁵ as shown in Figure 58-7, none of them were randomized and few were conducted in the modern era of effective PAH therapies. There have been two studies using warfarin conducted in the modern PAH therapy era; one resulted in better survival in idiopathic PAH, while the other was inconclusive.^{96,96a}

Despite the serious limitations in the existing data, published guidelines recommend that patients with idiopathic PAH be treated with warfarin.^{79,97} There is less guidance regarding the use of anticoagulation in other forms of PAH, such as that associated with congenital systemic-to-pulmonary shunts or associated with connective tissue diseases. Warfarin is clearly indicated for patients with Group 4 PAH (chronic thromboembolic disease). Other potential

Figure 58-7 Survival in patients with idiopathic pulmonary arterial hypertension based on acute vasoreactivity and treatment with calcium channel blockers or warfarin. In patients who were not vasoreactive (lower two lines), warfarin was associated with a modest survival advantage. (Redrawn from Rich S, Kaufmann RN, Levy PS: The effect of high doses of calcium-channel blockers on survival in primary pulmonary hypertension. *N Engl J Med* 327:76–81, 1992.)

situations in which warfarin may be considered include advanced heart failure or the presence of indwelling central venous catheters. Conversely, if there is increased risk for bleeding (thrombocytopenia, history of hemoptysis, or gastrointestinal bleeding), withholding anticoagulation is advised.

Factor Xa Inhibitors. Despite its pharmacologic limitations and need for frequent coagulation monitoring, warfarin, since 1954, has had virtually no competition as the clinical agent of choice for long-term anticoagulation. Recently, however, a novel group of oral anticoagulants—known as factor Xa inhibitors—has altered the current anticoagulation picture. Most clinical studies have compared the efficacy and safety of the standard regimen of parenteral enoxaparin followed by warfarin compared with a fixed-dose of a factor Xa inhibitor for treatment of either acute venous thromboembolism or atrial fibrillation; results to date indicate that long-term warfarin has equal anticoagulant effectiveness as one of several factor Xa inhibitors.⁹⁸ Furthermore, an experimental study of a factor Xa inhibitor using a rat model of PAH also showed beneficial results.⁹⁹ No effective antidote for serious bleeding related to factor Xa inhibitors is yet available, but major hemorrhage is infrequent. More information about this promising group of compounds is eagerly awaited.

Aspirin has also been considered potentially beneficial in PAH, based on evidence of platelet activation in PAH and on evidence of improved outcomes in animal models of pulmonary hypertension.¹⁰⁰ However, its use did not lead to improved outcomes in a randomized controlled clinical trial in PAH and it is therefore not recommended unless required for other indications.¹⁰¹

Supplemental Oxygen

The benefits of supplemental oxygen in PAH patients, unlike patients with pulmonary hypertension associated with lung diseases such as chronic obstructive pulmonary disease,^{102,103} are not clear. In fact, most PAH patients are not hypoxemic at rest. Mild hypoxemia, when present, is likely on the basis of reduced mixed venous oxygen saturation levels caused by low cardiac output with mild ventilation/perfusion inequality. The presence of more profound hypoxemia in a patient with PAH should raise suspicion for underlying parenchymal lung disease, systemic to pulmonary shunting, PVOD, pulmonary capillary hemangiomatosis, or pulmonary arteriovenous malformations as seen in pulmonary hypertension due to hereditary hemorrhagic telangiectasia. Of note, a patent foramen ovale, present in more than 20% of the population, can contribute to hypoxemia in pulmonary hypertension.

Although oxygen is a pulmonary vasodilator, there are no long-term studies supporting its efficacy. However, the consensus is that, if arterial PO_2 is less than 60 mm Hg or systemic arterial O_2 saturation is less than 90% at rest, supplemental oxygen is indicated. One exception to this approach is in patients with Eisenmenger syndrome, with hypoxemia due to right-to-left shunting; in this group, the use of supplemental oxygen may have negligible benefit.^{104,105} There is also no general agreement about whether exercise-only systemic arterial O_2 desaturation warrants oxygen supplementation. In addition, the “stigma”

of nasal cannulae for a PAH patient often limits compliance outside the home.

Diuretics

Diuretics have long been mainstays of therapy for heart failure, including right ventricular failure. Both total-body and intravascular volume overload are common in PAH patients. In pivotal trials of PAH drugs, the majority of patients were on chronic diuretic therapy.^{106,107}

In addition to causing symptomatic peripheral edema and renal¹⁰⁸ and hepatic congestion, volume overload of the right ventricle can cause compression of the left ventricle and contribute to decreased cardiac output and prerenal azotemia. Thus, it is a common observation that in decompensated PAH patients, aggressive diuresis leads to clinical and physiologic improvements. Despite the benefits of diuretics in PAH patients, there are no controlled studies to guide the clinician in using these agents.

A loop diuretic is frequently used first. Although furosemide is often the loop diuretic of choice, there is some evidence that torsemide might be more efficacious without increased side effects.¹⁰⁹ In addition, in patients with marked extravascular fluid accumulation and poor intestinal absorption, intravenous diuretic therapy is frequently needed. Anti-aldosterone drugs (e.g., spironolactone) are commonly combined with loop diuretics in PAH patients. Whether data suggesting a morbidity and mortality benefit of spironolactone in left-sided heart failure can be extrapolated to right-sided heart failure is not known.¹¹⁰

In some cases, the addition of a thiazide diuretic to the regimen is appropriate. The combination of metolazone and furosemide has been found by the authors to be effective in causing a brisk diuresis. However, marked hypokalemia can be seen with this regimen. Although it is possible that in some patients with PAH, the right ventricle is preload dependent and therefore over diuresis can be detrimental, this has not been the authors' experience. More often, aggressive diuresis (1- to 3-L negative fluid balance per day) leads to improvement in renal function and blood pressure.

Calcium Channel Antagonists

In 1958, Paul Wood¹⁴ first defined the clinical entity of pulmonary hypertension with reference to the “vasoconstrictive factor.” It is not surprising, then, that a search for pulmonary vasodilators as effective therapies ensued. Agents including phentolamine,¹¹¹ tolazine,¹¹² captopril,¹¹³ and hydralazine¹¹⁴ were evaluated in uncontrolled reports. Results, although variable, were not overwhelmingly favorable. No systematic studies of these medications were carried out. Out of the myriad of oral antihypertensive agents emerged calcium channel blockers. Ostensibly, this class of agents “made sense” for treating pulmonary hypertension. Calcium channel blockers have acceptable side effect profiles and are potent pulmonary as well as systemic vasodilator agents. The role of intracellular cytosolic calcium in the vasoconstriction of pulmonary artery smooth cells was well established. Thus, blocking influx of calcium into the cells seemed desirable.

In a highly quoted paper, Rich and associates¹¹⁵ described favorable survival in a subgroup of idiopathic PAH patients treated with either diltiazem or nifedipine. In that study,

patients manifesting acute pulmonary vasoreactivity with calcium channel blockers, defined as an acute decrease in mean pulmonary arterial pressure and PVR of at least 20%, had a 5-year survival of 94% (see Fig. 58-7). In contrast, patients who did not have an acute response had a 5-year survival of only 55%. In addition, the observed survival for the “acute responders” was significantly better than the survival predicted using an equation based on hemodynamics at time of diagnosis. Although not a placebo-controlled study, these data suggested a benefit with calcium channel blockers in some idiopathic PAH patients.

The Rich and associates’ study,¹¹⁵ although seminal, likely led to overuse of calcium channel blockers, not only for idiopathic PAH but for other forms of PAH. Calcium channel blockers are not selective pulmonary vasodilators and, in the setting of a nondilatable pulmonary vascular bed, the systemic vasodilating effects of these agents may lead to severe symptomatic hypotension. In addition, calcium channel blockers have potential negative inotropic effects. Thus, in patients with minimal or no acute pulmonary vasoreactivity, the negative effects of calcium channel blockers can become predominant, with potential for catastrophic consequences.

A subsequent large retrospective study by Sitbon and colleagues⁶⁹ has further narrowed the role of calcium channel blockers in patients with idiopathic PAH. In that study, 557 patients with idiopathic PAH were tested for acute pulmonary vasoreactivity using either intravenous prostacyclin (e.g., epoprostenol) or inhaled nitric oxide. Seventy patients (about 13%) had an acute response (at least a 20% fall in mean pulmonary artery pressure and PVR) and were treated with calcium channel blockers. However, only half of those “acute responders” (about 7% of the total) did “well” long term on calcium channel blockers, defined as being alive and in functional class 1 or 2 at 5-year follow-up. The long-term survivors had less severe disease as assessed by hemodynamics at baseline and had reached a lower mean pulmonary artery pressure with acute vasodilator challenge than those who failed with the long-term calcium channel blockers (33 mm Hg vs. 46 mm Hg). In other words, rather than the percent drop in mean pulmonary artery pressure during an acute test, the absolute mean pulmonary artery pressure reached appeared to be better in defining the patients who would benefit long-term with calcium channel blockers. These data have been codified into evidence-based guidelines,^{79,116} which define potential calcium channel blocker candidates as idiopathic PAH patients in whom, during an acute pulmonary vasoreactivity test, the mean pulmonary artery pressure decreases by at least 10 mm Hg to a level below 40 mm Hg, with no decrease in cardiac output.

The method for performing acute pulmonary vasoreactivity testing varies among pulmonary hypertension centers. Most frequently, one of three short-acting pulmonary vasodilators is used in the cardiac catheterization laboratory (i.e., inhaled nitric oxide, intravenous adenosine, or intravenous epoprostenol). Using a short-acting agent prevents refractory systemic hypotension that could result when a patient with PAH with minimal pulmonary vasoreactivity is given a systemic vasodilator. A distinct advantage of inhaled nitric oxide is the absence of systemic hemodynamic effects, the very rapid “on-off” properties of the drug

(i.e., half-life 20 seconds), and the absence of side effects. With inhaled nitric oxide, an acute pulmonary vasoreactivity test with repeat hemodynamic measurements can be accomplished in less than 10 minutes.

TARGETED THERAPIES

PAH-specific therapies have been available since 1995, when intravenous epoprostenol was approved by the U.S. Food and Drug Administration (FDA), based on the first prospective randomized controlled trial done in PAH. Since then, an additional 11 therapies have been approved for PAH: subcutaneous, inhaled, intravenous, and oral treprostinil; inhaled iloprost; the oral endothelin receptor antagonists bosentan, ambrisentan, and macitentan; the phosphodiesterase-5 inhibitors sildenafil and tadalafil; and the guanylate cyclase stimulator riociguat (Table 58-2). These therapies are targeted to offset the imbalance in endothelial-derived mediators seen in PAH: excessive endothelin-1 production, abnormal nitric oxide production, and deficient prostacyclin (Fig. 58-8).

Prostacyclin Analogues

Epoprostenol (Flolan/Veletri). Continuous intravenous infusions of prostacyclin (prostaglandin I₂, epoprostenol) produce sustained improvement in hemodynamics and exercise tolerance and prolonged survival. In the first randomized prospective study of epoprostenol,¹⁰⁶ 81 patients with New York Heart Association (NYHA) class III or IV symptoms, despite treatment with conventional therapy, were randomized either to continuous intravenous epoprostenol plus conventional therapy or to conventional therapy alone for 12 weeks. At 12 weeks, 6MWD, the primary end point, had improved in the continuous intravenous epoprostenol group by 32 m and decreased by 15 m in the conventional therapy group. There were also significant improvements in the epoprostenol group in hemodynamics, quality of life, and NYHA functional class. Eight patients died during the 12-week study, all in the conventional treatment group. Notably, this is the only randomized controlled PAH trial to date ever to show a significant effect on survival. A subsequent study found significant improvements in 6MWD, functional class, and exercise capacity in patients with scleroderma-associated PAH.¹¹⁷

Long-term follow-up studies have shown sustained benefits, including improved functional class and improved survival compared with historical controls. Five-year survival of greater than 60% has been seen in treated patients in two series,^{83,118} an improvement from the median survival in the “pre-epoprostenol” era of less than 3 years. Despite its clear benefits, chronic use of epoprostenol is complex and requires an indwelling central venous catheter, continuous-infusion pump, and daily preparation of the medication. In addition, there are numerous side effects including jaw claudication, leg and foot pain, diarrhea, rash, and weight loss occasionally with ascites. The complexities of dosing prostacyclin and assessing response to the therapy obligate a dedicated team, typically present only at large pulmonary hypertension centers.

Subcutaneous and Intravenous Treprostinil Sodium (Remodulin). Treprostinil sodium is a tricyclic benzidine

Head to head studies are lacking; comparing outcomes across studies is discouraged due to heterogeneity in response depending on baseline characteristics and other factors, particularly for 6MWD.

*Seraphin had a morbidity and mortality primary end point; study had a mean treatment duration of 85 weeks, 100 weeks, and 104 weeks (placebo, 3 mg macitentan, and 10 mg macitentan, respectively.)

Y: statistically significant, $P < 0.05$; N: $P > 0.05$; ♦, 1° end point; blank, not reported. analogue of prostacyclin that is chemically stable at room temperature and has a half-life of approximately 4 hours. Treprostinil was initially approved for continuous subcutaneous delivery, based on a double-blind, randomized, controlled trial that included 470 patients with idiopathic PAH (58%), PAH associated with connective tissue disease, or PAH associated with congenital systemic pulmonary shunts.¹¹⁹ As with other PAH trials, the primary outcome measure was exercise capacity defined as placebo-corrected improvement in 6MWD. The placebo-corrected improvement in 6MWD was 16 m ($P = 0.006$). Borg dyspnea scores, quality of life measures, and hemodynamics were also significantly improved in the treprostinil group compared with placebo.

Dosing of treprostinil in this trial and in all other systemic prostacyclin studies was left to the treating physician, with dose increases based on clinical response and side effects. Notably, walk distance improvement among treprostinil-treated patients varied by dosing quartile, with the greatest improvement seen in patients in the highest dosing quartile (>13.8 ng/kg/min). Infusion site pain was the major adverse event, experienced by 200 (85%) patients in the treprostinil group versus 62 (27%) in the placebo arm.

Other common side effects, all of which are seen with systemic prostacyclins as a class, included jaw pain, headache, and diarrhea.

Intravenous treprostinil was subsequently approved based on bioequivalence with subcutaneous treprostinil, with an intended use in patients not tolerating subcutaneous infusion. Intravenous treprostinil was later shown to lead to improvements in 6MWD versus placebo in one small randomized controlled clinical trial,¹²⁰ and it has also been the subject of several uncontrolled reports.^{121,122} Finally, sustained-release oral treprostinil is also now approved. Oral treprostinil led to significant improvement in 6MWD when taken as monotherapy in a 12-week PAH trial (FREEDOM-M),¹²³ but failed to lead to significant improvement in studies enrolling patients on background therapies (FREEDOM-C and C2).^{124,125} Hemodynamic effects and longer term results for other outcomes have not been reported.

Prostacyclin Dosing

There have been no studies formally comparing dosing strategies of continuous epoprostenol and treprostinil, and only very limited acute dose-ranging studies.¹²⁶

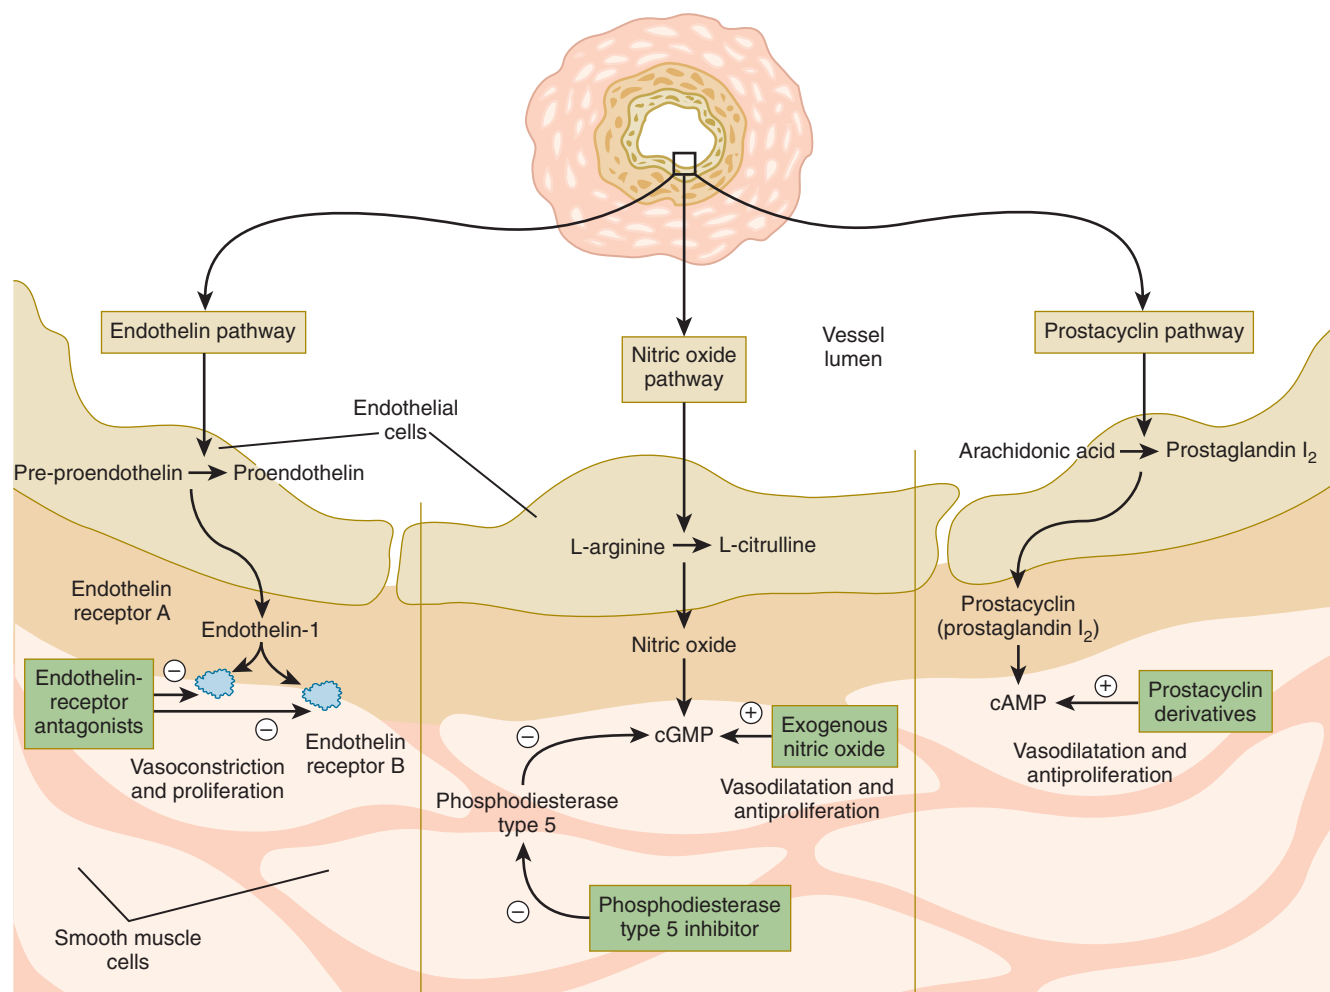

Figure 58-8 Schematic of three abnormal endothelial mediator pathways that are targeted by current therapies. cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate.

Nevertheless, there are observational data, particularly for treprostinil,¹²⁷ suggesting that higher doses are associated with improved outcomes. At the same time, other studies suggest that excessive dosing of epoprostenol can lead to an abnormally high cardiac output and more severe side effects.¹²⁸ Individualized dosing and periodic hemodynamic monitoring is therefore recommended for all patients on parenteral prostacyclins.¹²⁸

Intravenous epoprostenol is typically initiated in the hospital setting at 1 to 2 ng/kg/min and titrated up slowly over a few days to approximately 4 to 6 ng/kg/min, aiming to titrate up to an effective dose as quickly as possible, while at the same time avoiding excessive side effects of headache, flushing, nausea, and diarrhea, among others. After an initial inpatient titration, patients follow an outpatient dosing chart, continuing to increase on their own at approximately 3- to 7-day intervals until a target dose is reached. In clinical trials, the average dose achieved at 2 to 3 months (end of study) was 8 to 11 ng/kg/min.^{106,117,129} Long-term, average doses of 21 ng/kg/min at 1 year⁸³ and 35 ng/kg/min at approximately 1½ years¹¹⁸ have been reported.

Subcutaneous and intravenous treprostinil are initiated in a similar manner, but an overall higher dose is typically

targeted. This is based on the finding that, in one conversion study, patients who transitioned from epoprostenol to treprostinil required an approximately twofold higher dose of treprostinil to control their symptoms.¹²² Long-term open label studies of subcutaneous treprostinil have also suggested that achieving a subcutaneous treprostinil dose greater than 40 ng/kg/min is independently associated with improved survival.¹²⁷

Inhaled Iloprost (Ventavis) and Treprostinil (Tyvaso).

Iloprost, a stable prostacyclin analogue, was approved by the FDA as an inhaled formulation in 2004, based on the Aerosolized Iloprost Randomized study.¹³⁰ The primary outcome was a combined end point: at least 10% improvement in 6MWD, improvement in at least one NYHA functional class, and survival. This composite end point was achieved by 17% of patients in the iloprost group versus 5% in the placebo arm (estimated odds ratio of 4, $P < 0.05$). Positive secondary end points included improvement when compared with placebo in functional class, quality of life, and preinhalation pulmonary vascular resistance. Hemodynamic measures were also repeated following an iloprost treatment, and additional improvement in pulmonary vascular resistance compared to baseline in cardiac output and

pulmonary arterial pressure were seen. Inhaled iloprost is delivered via ultrasonic nebulizer at a starting dose of 2.5 µg delivered six to nine times daily and increased to 5 µg six to nine times daily if well-tolerated. Adverse events noted in the iloprost group during the clinical trial included syncope, flushing, jaw pain, and increased cough. Vital signs should be monitored during drug initiation; patients with preexisting hypotension (systemic blood pressure less than 85 mm Hg) should not receive iloprost.

Inhaled treprostinil received FDA approval in 2009, based on the TRIUMPH-1 study, a randomized controlled clinical trial involving 235 patients with PAH.¹³¹ Patients in the treatment arm showed a 20-m improvement in 6MWD compared with placebo ($P < 0.05$), and also showed improvement compared to placebo in secondary end points of *N-terminal brain natriuretic peptide* (NT-BNP) and quality of life, as assessed by the Minnesota Living with Heart Failure questionnaire. No significant improvement was seen in time to clinical worsening or functional class. Unlike prior studies, TRIUMPH-1 enrolled only patients receiving background therapy, requiring all patients to be on either an endothelin-1 antagonist or a phosphodiesterase-1 inhibitor. Inhaled treprostinil is delivered via an ultrasonic nebulizer, the Tyvaso Inhalation System, at a starting dose of three breaths four times daily. Dosage is increased by three breaths per treatment every 1 to 2 weeks, as tolerated, until a dose of nine breaths four times daily is reached. Adverse events in the clinical trial included cough, headache, and flushing.

Endothelin Receptor Antagonists

In humans, two *endothelin* (ET)-1 receptor subtypes are found, ET-A and ET-B. Antagonism of one or both receptors has been shown to be an effective treatment strategy for idiopathic PAH, with two FDA-approved therapies, bosentan and ambrisentan. Bosentan (Tracleer) is a nonpeptide oral ET-A and B receptor antagonist. Bosentan received FDA approval in 2001 based on two randomized controlled clinical trials showing significant improvement in 6MWD among bosentan versus placebo-treated patients.^{107,132} Pulmonary hemodynamics were evaluated in the smaller of the two studies, and significant improvement in right atrial pressure, pulmonary arterial pressure, pulmonary vascular resistance, and cardiac index were seen.¹³³ Other positive findings in both studies included improvement both in Borg dyspnea index and in clinical features. In addition to the two “registration” trials, bosentan has also shown benefit in two other randomized controlled clinical trials: BREATHE-5, enrolling patients with uncorrected congenital heart disease and Eisenmenger syndrome, and EARLY (Endothelin Antagonist Trial in Mildly Symptomatic Pulmonary Arterial Hypertension), a randomized controlled clinical trial in functional class 2 patients with PAH; results are shown in Table 58-2.

Ambrisentan (Letairis) is a specific ET-A receptor antagonist approved for PAH at doses of 5 or 10 mg once daily. Following a phase 2 dosing study showing favorable pulmonary hemodynamic effects,¹³⁴ two randomized, controlled trials of ambrisentan (*Ambrisentan in Pulmonary Arterial Hypertension, Randomized, Double-Blind, Placebo-Controlled, Multicenter, Efficacy Studies* [ARIES] 1: 5 mg, 10 mg, placebo; ARIES 2: 2.5 mg, 5 mg, placebo) enrolled

a total of 394 patients.¹³⁴ Both trials demonstrated benefits of ambrisentan on the primary end point of placebo-corrected improvement in 6MWD. In ARIES-2, there was a significant improvement in time to clinical worsening in the treatment group compared with placebo. There was a trend toward improvement in time to clinical worsening in the ARIES-1 study, but it was not statistically significant ($P = 0.3$).

Macitentan is a nonselective ET-A/ET-B antagonist with greater tissue penetration relative to bosentan that was evaluated in the SERAPHIN clinical trial. In SERAPHIN, patients were randomized 1:1:1 to placebo, macitentan 3 mg, or macitentan 10 mg, using a novel morbidity and mortality primary end point. Seven hundred and forty-two patients participated, and 64% were receiving a background PAH therapy. Overall, macitentan 3 mg and 10 mg resulted in a risk reduction for the primary end point of 30% and 45%, respectively, compared with placebo. Both doses of macitentan also led to significant reductions in time to PAH-related death or hospitalization and significant improvement compared with placebo in change in 6MWD at 6 months.¹³⁵

Sitaxsentan is an endothelin-1 antagonist that was shown to have beneficial effects in PAH, but it was removed from the market after it was linked to acute liver failure.

Endothelin-1 Antagonist Therapy

Endothelin-1 antagonists as a class are considered teratogenic, and therefore women of childbearing potential require monthly pregnancy testing and the use of two reliable forms of birth control during therapy. Increases in liver aminotransferases greater than eight times the upper limit of normal were also noted with bosentan therapy during randomized controlled clinical trials and, as a result, all patients receiving bosentan are required to undergo monthly liver function testing. The rate of liver function test abnormalities during ambrisentan administration has been found to be similar to that of the general population, and monthly testing is no longer required. Drug should be discontinued in patients taking either drug in whom liver function tests become abnormal during therapy, that is, aspartate aminotransferase or alanine transaminase elevations greater than fivefold normal or total bilirubin levels equal to or higher than twofold normal. In addition, for bosentan, aspartate aminotransferase or alanine transaminase elevations between three and five times the upper limit of normal require either a dose-reduction or drug cessation. Hemoglobin levels should also be monitored periodically, because anemia has been reported during therapy with endothelin-1 antagonists.

Endothelin-1 antagonists are well-tolerated by most patients, but significant peripheral edema was noted during the clinical trials, particularly in older patients. Close monitoring of volume status is therefore indicated during drug initiation and up-titration. Nasal congestion has also been reported, mainly with ambrisentan. Several significant drug interactions exist. For bosentan, both glyburide and cyclosporine are contraindicated, and strong cytochrome P450 inhibitors (rifampin, others) should be used with caution. For ambrisentan, the only clinically relevant interaction that has been identified is an increase in ambrisentan levels with cyclosporine; as a result, the ambrisentan dose

should be limited to 5 mg daily when taken with cyclosporine (see package inserts for additional details on pregnancy prevention, drug interactions, and laboratory monitoring).

Phosphodiesterase Type 5 Inhibitors

Sildenafil (Revatio) was evaluated in the SUPER-1 (*Sildenafil Use in Pulmonary Arterial Hypertension*) trial, a 12-week randomized, double-blind, placebo-controlled trial comparing placebo, 20 mg, 40 mg, and 80 mg three times daily.¹³⁶ There was a significant improvement in exercise capacity, functional class, and hemodynamics but not in time to clinical worsening. Walk distance improvement was similar across the three doses. However, hemodynamic improvement was greater with higher doses, as was the percentage of patients with improved functional class (7% in placebo group, 28% in the 20-mg group, 36% in the 40-mg group, and 42% in the 80-mg group). Despite these trends, the only U.S. FDA and European Medicines Association approved dosage is 20 mg three times daily.

Tadalafil. Tadalafil (Adcirca) was approved in 2009 based on the PHIRST trial, a 16-week study of 2.5 mg, 10 mg, 20 mg, and 40 mg tadalafil versus placebo.¹³⁷ Tadalafil 40 mg led to improvement in exercise capacity, quality of life, hemodynamics, and time to clinical worsening. Smaller but statistically significant improvement in walk distance was also seen for the 10-mg and 20-mg groups, but not for the 2.5-mg group; 40 mg once daily is the recommended dosage.

Phosphodiesterase-5 Inhibitor Therapy

Sildenafil and tadalafil are selective inhibitors of cyclic guanosine monophosphate-specific phosphodiesterase-5, an enzyme that promotes the breakdown of cyclic guanosine monophosphate. Both sildenafil and tadalafil appear to be well-tolerated clinically, and there were no significant laboratory abnormalities noted during the pivotal clinical trials. Many drug interactions have been described and should be considered before initiation: use with nitrates is contraindicated due to risk of excessive hypotension, and use with

potent cytochrome P-450 inhibitors should be avoided with both drugs (see package inserts for details).

Common adverse events during the clinical trials included headache, myalgias, flushing, epistaxis, and dyspepsia. Both drugs can be initiated at their approved dosage (sildenafil 20 mg three times daily or tadalafil 40 mg daily) but, at the authors' centers, tadalafil is initiated at a 20-mg dose for the first week in an attempt to lessen headaches and other side effects.

Impaired vision and hearing have been reported with the use of phosphodiesterase-5 inhibitors. Mild vision changes including particularly color vision changes are thought to relate to cross reactivity with and inhibition of retinal phosphodiesterase-6. More severe vision changes including sudden vision loss have also been reported, and hearing loss has been reported as well; both are of unclear mechanism.¹³⁸ Patients should seek immediate medical attention in the event of sudden loss of vision in one or both eyes or with sudden changes in hearing.

Soluble Guanylyl Cyclase Activators

Riociguat, a direct activator of guanylyl cyclase, increases levels of cyclic GMP by stimulating its synthesis.¹³⁹ It has been studied in two phase 3 randomized controlled clinical trials, PATENT, a study in PAH, and CHEST, a study in patients with chronic thromboembolic disease that is either inoperable or persistent following pulmonary thromboendarterectomy. In both studies, riociguat led to improvement in the primary end point, change in 6MWD versus placebo at 12 weeks (PATENT) or 16 weeks (CHEST), and to improvement in a number of secondary end points including PVR, NT-BNP level, and WHO functional class.¹⁴⁰

COMBINATION THERAPY

There is strong rationale for combining drugs to treat idiopathic PAH, and an increasing number of clinical trials show benefit with this approach (Table 58-3). In current practice, about 52% of patients receive combination therapy, based on data from the REVEAL registry.⁹⁴

Table 58-3 Combination Therapy and Select Other Clinical Trials in Pulmonary Arterial Hypertension

The PACES (*Pulmonary Arterial Hypertension Combination Study of Epoprostenol and Sildenafil*) trial evaluated sildenafil versus placebo as add-on therapy in 267 patients on epoprostenol. Subjects were randomized to either additional sildenafil 80 mg three times daily or placebo for 16 weeks.¹⁴¹ The trial demonstrated a placebo-corrected 6MWD improvement in the sildenafil-epoprostenol group of 29 m. In addition, significant hemodynamic improvements and improvement in time to clinical worsening were seen in the sildenafil-epoprostenol group compared with the placebo-epoprostenol group. Although mortality was not a prespecified end point, there were seven deaths during the trial, all of which were in the placebo-epoprostenol group. Subsequently, multiple additional randomized controlled clinical studies that involved combination therapy have been conducted and are either in process or have recently been completed (see [Tables 58-2](#) and [58-3](#)).

Perhaps not surprisingly, the incremental improvements in 6MWD obtained by adding an agent in combination therapy studies have been smaller than those reported with the first agent in monotherapy studies. This observation has raised questions in some cases about whether very small improvements in 6MWD alone are sufficient evidence of benefit for novel drugs in PAH, particularly in studies where no improvement is seen in other important secondary end points such as clinical worsening, functional class and/or quality of life.¹⁴²⁻¹⁴⁴ As a result, alternative study designs, including long-term morbidity and mortality trials are being used in some current and recently completed clinical trials. Additionally, the optimal *timing* of combination therapy is unclear. Several ongoing studies are investigating the feasibility and efficacy of up-front combination therapy.

LUNG TRANSPLANTATION

In patients failing maximal medical therapy, lung transplantation is the “ultimate” option (see Chapter 106). According to the International Society of Heart and Lung Transplantation, current recommendations for consideration of transplantation in PAH include persistent NYHA class III or IV on maximal medical therapy, low or declining 6MWD, failing therapy with intravenous epoprostenol, cardiac failure with cardiac index less than 2 L/min/m², and elevated right atrial pressure (>15 mm Hg).¹⁴⁵ Additionally, all patients with PVOD should be referred for transplant evaluation at the time of diagnosis, given its poor response to therapy.

The current lung allocation scoring system was designed to improve the overall likelihood of transplant and to reduce wait list and posttransplant mortality compared with the prior system. Patients are now prioritized based on a computer-generated severity score rather than the amount of time they have been on the waiting list. As a whole, the system appears to have achieved many of its goals, because the percentage of patients transplanted within 1 year of listing has increased substantially and mortality on the waiting list has fallen.

However, this has not been the case in PAH. Patients with PAH have lower lung allocation scores and lower transplantation rates than do patients with other lung diseases and higher wait list mortality.¹⁴⁶ Modifications to the lung allocation score have been proposed, including the addition

of prognostic markers that have relevance in PAH, rather than relying on factors that are not very prognostic in PAH, such as pulmonary function test results and oxygen requirements. In the meantime, “exceptions” to the lung allocation score can be requested for patients who are deteriorating on optimal therapy with a right atrial pressure above 15 mm Hg or a cardiac index below 1.8 L/min/m².

One-year survival after lung transplantation for pulmonary hypertension is approximately 70%, which is lower than that of other groups due in part to higher rates of immediate posttransplant complications. In the long term, PAH patients do as well or better than patients transplanted for other lung diseases, with those surviving the first year having a conditional average survival of 10 years.¹⁴⁷

OVERALL THERAPEUTIC STRATEGY

With multiple effective medical therapies and lung transplantation available for treatment of PAH, how does one decide what therapy to use, when to reassess, when to add or change therapy, and what to add or change? Several consensus committees have attempted to evaluate the evidence for approved therapies.^{79,148} The most recent guidelines suggest making treatment decisions based on both symptoms and results of prognostic tests that are most predictive of outcomes in PAH.

Supportive therapies including warfarin, need for diuretics, and oxygen are considered. An acute vasoreactivity test is recommended for patients with idiopathic PAH and, if a positive response is seen, calcium channel blocker treatment is recommended. For patients with idiopathic PAH without acute vasoreactivity and for other PAH groups in general, the initial treatment decision is made based on PAH severity. Patients at highest risk for death or clinical worsening are treated with a systemic prostacyclin as the initial therapy, while lower risk patients may be offered therapy with an oral or in some cases an inhaled medication. There is no single prognostic marker that is sufficient in making this decision, but a combination of clinical impression, functional class, 6MWD, laboratory results, catheterization results, and assessment of right ventricular function by imaging can be used to assess risk ([Table 58-4](#)).

Consideration of combination therapy is also recommended for patients who have an inadequate response to a single agent, with response typically assessed at 3 to 6 months. Adding a second agent rather than switching from one class of medication to another is generally recommended, given the lack of clinical trial data investigating the latter approach.

SURVIVAL

Long-term survival data are emerging in the era of idiopathic PAH treatment. In patients treated with epoprostenol, two papers demonstrated survival estimates of approximately 60% at 3 years.^{83,118} In these retrospective studies, favorable survival was best predicted by response to therapy (improvement in 6MWD, functional class, and PVR). Observational survival data over several years is also available for other specific therapies and for PAH in general, based on the extension studies from several clinical trials and from cohort studies such as the REVEAL registry. For

Table 58-4 Variables with Established Importance for Assessing Pulmonary Arterial Hypertension Disease Severity

Determinants of Prognosis	Better Prognosis	Worse Prognosis
Clinical evidence of RV failure	No	Yes
Rate of progression of symptoms	Slow	Rapid
Syncope	No	Yes
WHO functional class	I, II	IV
6MWD	Longer (>500 m)*	Shorter (<300 m)
Cardiopulmonary exercise testing	Peak O ₂ consumption > 15 mL/min/kg	Peak O ₂ consumption < 12 mL/min/kg
BNP/NT-proBNP plasma levels	Normal or near-normal	Very elevated and rising
Echocardiographic findings†	No pericardial effusion TAPSE‡ >2.0 cm	Pericardial effusion TAPSE‡ < 1.5 cm
Hemodynamics	RAP < 8 mm Hg and CI ≥ 2.5 L/min/m ²	RAP > 15 mm Hg or CI ≤ 2 L/min/m ²

*Depending on age.

†TAPSE and pericardial effusion have been selected because they can be measured in the majority of the patients.

BNP, brain natriuretic peptide; CI, cardiac index; 6MWD, 6-minute walking distance; RAP, right atrial pressure; TAPSE, tricuspid annular plane systolic excursion. Adapted from McLaughlin VV, McGoon MD: Pulmonary arterial hypertension. *Circulation* 114:1417–1431, 2006.

example, in 169 idiopathic PAH patients enrolled in the two pivotal trials of bosentan, estimated survival at 1 and 2 years was 96% and 89%, respectively, compared with the predicted survival of 69% and 57%^{107,149} (based on a validated equation calculating predicted survival from baseline hemodynamics). Similarly, survival times for patients with idiopathic PAH in REVEAL on any PAH therapy were 91%, 74%, and 65% at 1, 3, and 5 years.¹⁵⁰

ACKNOWLEDGMENTS

The authors would like to thank Dr. Lewis Rubin for his contributions to prior editions of this chapter.

Key Points

- Pulmonary hypertension has been classified into five World Health Organization groups: (1) pulmonary arterial hypertension, (2) pulmonary hypertension with heart disease, (3) pulmonary hypertension with lung disease, (4) pulmonary hypertension with pulmonary thromboembolism, and (5) miscellaneous.
- Group 1 Pulmonary arterial hypertension has further been classified as (1) idiopathic, (2) heritable, (3) related to other conditions, (4) primary pulmonary hypertension of the newborn, and (5) pulmonary veno-occlusive disease.
- Heritable pulmonary hypertension has been associated with mutations in *BMPR2*, *ALK1* and other genes, but pulmonary hypertension does not develop in all carriers, indicating other defects or insults are required.
- The basis for treatment of idiopathic pulmonary artery hypertension stems from its known deficiencies in prostacyclin and nitric oxide release and excess endothelin-1.
- Pulmonary hypertension can be suspected based on physical examination, chest radiology, electrocardiography, and echocardiography, but establishing the diagnosis with certainty requires a right-sided cardiac catheterization to exclude left heart failure,

determine severity, and assess response to pulmonary vasodilators.

- Targeted therapy with the prostacyclins, phosphodiesterase inhibitors, and endothelin receptor antagonists has made major improvements in the life of patients with pulmonary artery hypertension and, based on meta-analysis and observational studies, has led to improvements in survival.

TREATMENT

Treatments Useful in All Patients with PH-LD

Treatments That May Be Considered in Selected Patients

Treatment of Decompensated RV Failure

INTRODUCTION

This chapter will focus on the *pulmonary hypertension* (PH) that results from chronic lung diseases. This is a common and significant clinical complication of lung disease, and it is a PH that differs from the other types both in causation and in therapeutic approach. The current (2013) “Updated Clinical Classification of Pulmonary Hypertension” (Table 59-1) serves to define the terminology used in this chapter and in Chapter 58.¹ These groups are classified according to the underlying pathologic process that leads to PH. Note that the term *pulmonary arterial hypertension* (PAH) refers specifically to diseases in group 1, including idiopathic PAH. PH is used for the PH in groups 2, 3, 4, and 5. *PH due to lung disease* (PH-LD) is categorized in group 3. This is the PH that will be the topic of this chapter. Group 1 PH (PAH) is covered in Chapter 58, and group 4 PH (chronic thromboembolic PH) is covered in Chapter 57.

In previous editions the title of this chapter was “Cor Pulmonale.” Historically, there has been no consensus about the definition of the term *cor pulmonale*.^{2,3} Today the term *cor pulmonale* generally refers to abnormalities of right heart structure and function that develop in the setting of lung disease and/or hypoxemia, including parenchymal lung disease, ventilatory impairment, or high-altitude hypoxemia. *Cor pulmonale* develops secondary to pulmonary hypertension, characterized by elevations in *pulmonary vascular resistance* (PVR) and in *pulmonary artery pressure* (PPA), which causes increased right ventricular afterload and, in susceptible patients, eventually progresses to right ventricular failure.

The development of PH and subsequent *cor pulmonale* in patients with lung disease is clinically important because it is common and is associated with increased morbidity and mortality. In one large community-based series, PH-LD was the second most common cause of PH after left heart disease⁴ (Fig. 59-1). Available data show that nearly all types of advanced lung disease can be

complicated by PH and eventually progress to right heart failure. However, patients with *chronic obstructive pulmonary disease* (COPD) and *idiopathic pulmonary fibrosis* (IPF) will be the focus of this chapter. As in all patients with PH, a thorough and exhaustive diagnostic evaluation is critical to determine the primary cause of PH and to identify concomitant conditions that might worsen PH and right heart failure. The different groups of PH affect different areas of the pulmonary circulation (Fig. 59-2); nonetheless, even those that affect the pulmonary arterioles have a different underlying pathologic process and response to treatment. Distinguishing between group 3 PH-LD and group 1 PAH is especially important because these diseases are pathologically and clinically distinct and respond differently to treatment. The best treatment of patients with PH-LD and subsequent *cor pulmonale* continues to be optimal management of the underlying lung disease, correction of hypoxemia, and timely consideration for lung transplantation.

EPIDEMIOLOGY OF PULMONARY HYPERTENSION DUE TO LUNG DISEASE

PREVALENCE

The prevalence of PH among patients with known lung disease has been assessed in numerous studies. Available studies suffer from significant limitations, including inconsistent definitions of PH and frequent use of echocardiography rather than right heart catheterization to assess hemodynamics. Additionally, patient cohorts are often heterogeneous, and comprehensive assessments to exclude other important and common causes of PH (e.g., chronic thromboembolic PH, and left heart disease) generally have not been performed.

Table 59-1 Group 3 PH as Outlined in the Fifth World Symposium Clinical Classification of Pulmonary Hypertension (2013)*

GROUP 1: PULMONARY ARTERIAL HYPERTENSION (PAH)

GROUP 1': PULMONARY VENO-OCCLUSIVE DISEASE (PVOD) AND/OR PULMONARY CAPILLARY HEMANGIOMATOSIS (PCH)

GROUP 1'' PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN

GROUP 2: PULMONARY HYPERTENSION DUE TO LEFT HEART DISEASE

GROUP 3: PULMONARY HYPERTENSION DUE TO LUNG DISEASES AND/OR HYPOXIA

COPD

Interstitial lung disease

Other pulmonary diseases with mixed restrictive and obstructive pattern

Sleep-disordered breathing

Alveolar hypoventilation disorders

Chronic exposure to high altitude

Developmental lung diseases

GROUP 4: CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION (CTEPH)

GROUP 5: PULMONARY HYPERTENSION WITH UNCLEAR MULTIFACTORIAL MECHANISMS

*See Table 58-1 for complete classification.

Figure 59-1 Prevalence of pulmonary hypertension by cause in a large community-based study. Note that left heart disease is by far the most common cause of pulmonary hypertension, whereas chronic lung disease is the second most frequent cause. (Data from Strange G, Playford D, Stewart S, et al: Pulmonary hypertension: prevalence and mortality in the Armadale echocardiography cohort. *Heart* 98:1805–1811, 2012.)

Figure 59-2 Localization of abnormalities in pulmonary hypertension. Pathologic changes that result in pulmonary hypertension from group 3 chronic lung disease (PH-LD) primarily target pulmonary arterioles, the same location as abnormalities in group 1 pulmonary arterial hypertension (PAH) and group 4 chronic thromboembolic pulmonary hypertension (CTEPH). Abnormalities that result in PH in group 2 left heart disease (PH-LHD) are found mostly on the venous side of the pulmonary circulation. AO, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary arteries; PC, pulmonary capillaries; PV, pulmonary veins; RA, right atrium; RV, right ventricle; VC, vena cavae.

CHRONIC OBSTRUCTIVE PULMONARY DISEASE

The lung disease most frequently associated with PH is COPD (PH-COPD), which is by far the most common cause of cor pulmonale, accounting for more than 80% of all cases.⁵ However, the estimated prevalence of PH in patients with known COPD varies dramatically—from 2.7% to 90.8%^{6,7}—depending on the definition of PH and the study population.

The standard definition of PH in this population, as in other populations, is a *mean P_{PA}* (*P_{PA}*) greater than 25 mm Hg, although some studies have used different cutoff values (e.g., 20 mm Hg). The gold standard for this measurement is the right heart catheterization. A more convenient but less accurate measurement is by echocardiography which requires a tricuspid regurgitant jet to measure the pressure gradient across the valve and thus estimate *pulmonary artery systolic pressure* (PASP). Echocardiographic estimates of PASP are possible only in those patients with a measurable tricuspid regurgitant jet and are known to overestimate and underestimate true PASP.

An early study of right heart catheterization in 175 patients with severe COPD showed that 35.4% of patients had a *P_{PA}* greater than or equal to 20 mm Hg and 9.7% had a *P_{PA}* greater than 30 mm Hg.⁸ In another study, invasive hemodynamic values were assessed in 120 patients with severe airflow obstruction (mean FEV₁ 27% of predicted) at the time of enrollment in the National Emphysema Treatment Trial. In this cohort, 90.8% of patients had a *P_{PA}* greater than 20 mm Hg, but only 5% had a *P_{PA}* greater than 35 mm Hg. Importantly, *pulmonary capillary wedge pressure* (PPW) was greater than 12 mm Hg in 61.4% of patients and greater than 20 mm Hg in 6.4% of patients, suggesting that left-sided heart failure was an important contributor to PH in this population.⁷ To assess the prevalence of PH in an outpatient population with stable COPD, echocardiography was performed in 159 patients to estimate PASP. Tricuspid regurgitation was adequate to estimate PASP in 105 patients, and, of those, 60% had a PASP greater than or equal to 35 mm Hg and were classified as having PH.⁹ Patients with PASP greater than or equal to 35 mm Hg were older and had lower FEV₁ and DL_{CO} values.

Figure 59-3 Severity of pulmonary hypertension in patients with COPD in a large French cohort. Although elevation in pulmonary artery pressure is common in patients with COPD, severe pulmonary hypertension is unusual. For many of the patients with severe pulmonary hypertension in this cohort, another medical problem such as chronic thromboembolic disease or left heart disease was judged to be the primary cause of pulmonary hypertension. (From Chaouat A, Naeije R, Weitzenblum E: Pulmonary hypertension in COPD. *Eur Respir J* 32:1371–1385, 2008. Fig. 1; based on data from Chaouat A, Bugnet AS, Kadaoui N, et al: Severe pulmonary hypertension and chronic obstructive pulmonary disease. *Am J Respir Crit Care Med* 172:189–194, 2005. doi:10.1183/09031936.00015608. Reproduced with permission of the European Respiratory Society.)

In one well-designed study,⁶ 998 patients underwent right heart catheterization at a referral center in France as part of evaluation for chronic respiratory failure; severe PH, defined as $\overline{\text{PPA}}$ greater than or equal to 40 mm Hg, was diagnosed in 27 patients (2.7%) (Fig. 59-3). Another cause of PH was found in 16 patients, resulting in a final diagnosis of PH secondary to COPD in only 11 patients (1.1%). Compared to other patients in the cohort, the patients with severe PH had lower DLCO and arterial PCO_2 and PO_2 values. Patients with severe PH also had lower cardiac indices and higher right atrial pressures, suggesting reduced right ventricular function.

These studies demonstrate that mild PH is common among stable outpatients with COPD. Importantly, more severe hemodynamic abnormalities were observed only in a very small number of patients, and, among those patients, other causes of PH were common.

Examining cohorts of patients undergoing evaluation for lung transplantation is useful because they include a relatively homogenous patient population with complete hemodynamic data; however, they represent a cohort with particularly advanced lung disease in whom PH might be expected to be more frequent and more severe.

A recent retrospective study used right heart catheterization data from the Organ Procurement and Transplantation Network database to study PH in 4930 patients with COPD listed for lung transplantation.¹⁰ The prevalence of mild and moderate PH defined as a $\overline{\text{PPA}}$ greater than or equal to 25 mm Hg and less than 35 mm Hg with a PPw less than or equal to 15 mm Hg was 30.4%, and the prevalence of severe PH defined as a $\overline{\text{PPA}}$ greater than or equal to 35 mm Hg with a wedge pressure less than or equal to 15 mm Hg was 4.0%. A significant number of patients, 17.2%, had a $\overline{\text{PPA}}$ greater than or equal to 25 mm Hg but

also had a PPw greater than 15 mm Hg. Moreover, the PPw was greater than 15 mm Hg in about 50% of the patients with $\overline{\text{PPA}}$ greater than or equal to 31 mm Hg, demonstrating that elevated left heart filling pressures are common in this population and may contribute significantly to PH. Findings were similar in another study of 409 patients with COPD undergoing evaluation for lung transplantation in Denmark.¹¹ In this study 36% of patients had PH with a $\overline{\text{PPA}}$ greater than or equal to 25 mm Hg, PPw less than or equal to 15 mm Hg, and 13% had a $\overline{\text{PPA}}$ greater than or equal to 25 mm Hg but also had a PPw greater than 15 mm Hg. Only 6 (1.5%) patients had a $\overline{\text{PPA}}$ greater than or equal to 40 mm Hg. In this population, PH was associated with the presence of more severe hypoxemia and lower FEV_1 values. Similar to the previously discussed studies, patients being evaluated for transplant frequently have elevations in $\overline{\text{PPA}}$; however, there is a low prevalence of severe PH, and a significant proportion of patients have elevated PPw, which suggests a contribution from left-sided heart failure.

There are limited longitudinal data concerning PH-COPD; however, the progression of PH in these patients appears to be slow.¹² Among patients who are found to have normal $\overline{\text{PPA}}$ at rest, changes in pulmonary hemodynamics are frequently minimal over time. For example, in a group of 61 patients without initial PH, all of whom had arterial hypoxemia, a second right heart catheterization almost 8 years later revealed an average change in $\overline{\text{PPA}}$ from 15.5 ± 2.4 to 19.6 ± 7.0 mm Hg.¹³ In a second group of 32 patients who had PH on their first catheterization, there was a nonsignificant rise in $\overline{\text{PPA}}$, from 27.7 ± 6.0 to 31.0 ± 9.3 mm Hg, after 5 years.¹⁴ An increase of 5 mm Hg or more was seen in approximately one third of patients and was clearly related to worsening hypoxemia.

In patients with COPD the presence of PH is clinically important because it is associated with worse exercise tolerance and survival compared to COPD patients without PH. In the retrospective organ procurement database study, 6-minute walk distance (6MWD) was on average 28 m less in patients with PH compared to those with normal hemodynamics; in addition, $\overline{\text{PPA}}$ was an independent predictor of a low 6MWD in a multivariate model. In this study, adjusted risk for death on the transplant list was significantly increased in patients with PH (hazard ratio 1.27).¹⁰ Findings were similar in a study of 362 patients at a single center undergoing transplant evaluation. In multivariate analysis, higher $\overline{\text{PPA}}$ was associated with a shorter 6MWD, including a reduction of 11 m for every 5 mm Hg increase in $\overline{\text{PPA}}$.¹⁵ In the Danish cohort, PH did not affect 6MWD but did affect the survival rate; the survival rate at 5 years was 37% for patients with PH compared to 63% in patients without PH ($P = 0.016$). In this cohort the presence of PH did not affect outcomes following lung transplantation.¹¹ Among the 11 patients with severe PH in the French COPD cohort, exertional dyspnea was significantly worse and survival was significantly shorter compared to patients without severe PH.⁶ In another study, the effects of PH on survival were assessed in a cohort of 84 patients who underwent hemodynamic evaluation before institution of long-term oxygen therapy. Adjusted 5-year survival rate was 62% for patients with an initial $\overline{\text{PPA}}$ of 25 mm Hg or less, whereas it was only 36% in the 40 remaining patients who had an

initial $\overline{\text{PpA}}$ higher than 25 mm Hg. In this cohort, initial $\overline{\text{PpA}}$ was a better prognostic indicator than either the FEV_1 , the degree of hypoxemia, or the level of hypercapnia.¹⁶ The results of a study of 101 patients with PH and COPD at a PH referral center came to similar conclusions. Survival at 3 years was 33% in patients with $\overline{\text{PpA}}$ greater than or equal to 40 mm Hg versus 55% in patients with $\overline{\text{PpA}}$ of 25 to 39 mm Hg. In a multivariate analysis, age, DL_{CO} , mixed venous oxygen saturation, and World Health Organization functional classification were independent predictors of survival.¹⁷ These findings suggest that even mild PH may have a significant negative impact on exercise tolerance and survival and that the presence of PH may be a more important prognostic factor than the severity of lung disease.

IDIOPATHIC PULMONARY FIBROSIS

Most of the available data regarding PH associated with IPF (PH-IPF) comes from patients undergoing evaluation for lung transplantation. In a study of 79 patients with IPF referred for lung transplantation who had a right heart catheterization, 32% (25 of 79) had PH documented by a $\overline{\text{PpA}}$ greater than 25 mm Hg.¹⁸ In another cohort of 124 patients undergoing evaluation for lung transplant at the Cleveland Clinic, 44% (54 of 124) had a $\overline{\text{PpA}}$ greater than or equal to 25 mm Hg.¹⁹ A study of 101 Japanese patients with IPF who underwent right heart catheterization showed similar results with a prevalence of $\overline{\text{PpA}}$ greater than 25 mm Hg of 15% (15 of 101).²⁰ These studies show an overall high rate of PH-IPF in patients with advanced IPF.

The presence of PH-IPF is associated with worsening symptoms, functional impairment, and increased morbidity and mortality.^{18,21-23} In a retrospective study of 136 patients with IPF, the median survival of those with estimated PASP of greater than 50 mm Hg by echocardiography was less than 1 year ($P = 0.009$) compared to 4.8 years for patients without PH (PASP < 35 mm Hg), and 4.1 years for patients with mild PH (PASP 36 to 50 mm Hg).²² The 1-year survival rate in 79 patients undergoing lung transplant evaluation was lower (72%) in those patients with PH compared to IPF patients without PH (94.5%; $P = 0.002$).¹⁸ Furthermore, patients with PH who had lower DL_{CO} values were more likely to require supplemental oxygen, to have shorter 6MWD, and to exhibit a lower arterial oxygen saturation nadir. In one study of 78 patients with PH-IPF, using a cutoff based on a receiver operating curve, the 5-year survival rate was 62% for the group ($n = 37$) with $\overline{\text{PpA}}$ values less than 17 mm Hg compared to 17% for the group ($n = 24$) with $\overline{\text{PpA}}$ values greater than 17 mm Hg ($P < 0.001$). The relative risk for death was significantly higher at 2.2 for the high- $\overline{\text{PpA}}$ group.¹⁹ According to an analysis of 2972 patients with advanced IPF listed for lung transplantation between 1995 and 2004, those with PH were 1.6 times more likely to die after being listed for transplantation compared to those without PH.²³ These data suggest that, similar to patients with PH-COPD, the consequences of PH-IPF are serious and that even mild increases in $\overline{\text{PpA}}$ are associated with increased mortality.

The presence of pretransplant PH may even have a significant effect on posttransplant outcomes. In a cohort of 126 patients, those who developed primary graft dysfunction had high pretransplant $\overline{\text{PpA}}$ values, and each 10 mm Hg

increase in $\overline{\text{PpA}}$ was associated with an increase in the odds of primary graft dysfunction by 1.64.²⁴

OTHER LUNG DISEASES

Patients with the syndrome of combined emphysema and pulmonary fibrosis seem to be at particularly high risk for developing PH, with grave consequences. Prevalence of PH in these patients has been described to be between 30% and 50%; this group had markedly reduced survival.^{25,26} In one retrospective series of 40 patients with combined emphysema and pulmonary fibrosis, elevated $\overline{\text{PpA}}$ above 40 mm Hg was present in 48% of patients.^{26a} Patients had severe symptoms, 85% with New York Heart Association functional class III or IV, and an average 6MWD of 244 m. Outcomes in this population were poor. For those with a PVR above the median value, one year survival was 48% while, for those with a PVR below the median, one year survival was 100%.

In patients without parenchymal lung disease, hypoxemia from high altitude, obstructive sleep apnea (OSA), and obesity hypoventilation syndrome are important independent causes of PH by themselves, or they may contribute significantly to PH from other causes. Because of the large number of individuals who live and visit at high altitudes, environmental hypoxemia related to altitude may be one of the most common causes of PH worldwide.^{27,28} OSA appears to be an increasingly common cause of PH. In multiple studies of patients with OSA, the prevalence of PH ranges from 20% to 40% with mild elevation in $\overline{\text{PpA}}$ (23-32 mm Hg). Interestingly, this PH may be reversible; a well-designed prospective trial²⁹ showed that treatment with continuous positive airway pressure over 6 months reduced $\overline{\text{PpA}}$ in patients with OSA.²⁹ Obesity hypoventilation syndrome, which is increasingly common worldwide, also causes PH. The prevalence of $\overline{\text{PpA}}$ greater than 20 mm Hg among 29 patients with obesity hypoventilation syndrome was 59% in a cohort of untreated patients.³⁰ In another study of 21 patients with obesity hypoventilation syndrome treated with noninvasive positive pressure ventilation, the prevalence of $\overline{\text{PpA}}$ greater than 20 mm Hg was 81%, although only 3 patients (14%) had severe PH with $\overline{\text{PpA}}$ greater than 35 mm Hg. In this study, $\overline{\text{PpA}}$ correlated negatively with use of noninvasive positive pressure ventilation, and, by multivariate regression, the presence of PH was an independent predictor of poor physical functioning.³¹

Case reports and small series describing PH as a complication of a variety of other lung diseases have been published. These conditions will not be specifically discussed here but may include sarcoidosis, Langerhans cell histiocytosis, lymphangioleiomyomatosis, adult bronchopulmonary dysplasia, and cystic fibrosis. Limited published data suggest that development of PH in all of these conditions is associated with worse outcomes.^{32-32b}

PATHOLOGIC CHANGES AND PATHOGENESIS

Although the mechanisms underlying the development and progression of PH in patients with lung disease are

incompletely understood, they appear to be multifactorial and to vary with the underlying lung disease. It is likely that early vascular endothelial injury is caused by factors such as hypoxemia and inflammation leading to endothelial dysfunction and subsequently the development of structural vascular changes. These abnormalities lead to an increase in PVR and a subsequent increase in PPA.

PULMONARY VASCULAR REMODELING

Many of the individual elements of pulmonary vascular remodeling seen in PH-LD are similar to those seen in PAH. The primary differentiating pathologic feature is that patients with PH-LD generally do not have the plexiform lesions that are seen in patients with PAH.³⁴ Multiple mechanisms most likely contribute to the development of the vascular pathologic features observed in PH-LD, which, once established, contribute to elevated PPA.^{35,35a}

There are a variety of pathologic vascular changes described in PH-LD that vary with the type of lung disease and overlap significantly with the changes seen in PAH (Fig. 59-4). Knowledge about pathologic changes in PH-LD comes from autopsy series and studies of explanted lungs

at the time of transplant. A characteristic feature often seen in PH-LD that is also seen in PAH is the extension of smooth muscle into small pulmonary arterioles less than 80 μm , where it is not found in healthy lungs. This is termed “muscularization” and is characterized by circularly oriented smooth muscle cells between the two layers of elastic lamina.³⁶ Muscularization may result from hypertrophy and proliferation of existing smooth muscle and from development of new smooth muscle cells. Another common finding in lungs from patients with PH-LD that overlaps with PAH is proliferation of the intimal layers of the pulmonary arterioles. Inflammation and thrombosis in situ may also be seen.

Pathologic changes that are unique to PH-LD are those that are associated with the underlying lung disease. In patients with PH-COPD there is destruction of alveoli and concomitant destruction of the associated pulmonary vasculature, which causes a further reduction in the pulmonary vascular cross-sectional area, leading to an increase in PVR.³⁷ A unique finding in patients with PH-IPF is that vascular changes are seen both in areas of lung fibrosis and in areas of normal lung, though the vascular changes in areas of normal lung are less severe and found in a smaller

Figure 59-4 Histologic appearance of normal and abnormal pulmonary arterioles. **A**, Normal pulmonary arteriole. Characteristic features include a large lumen relative to wall thickness, a single elastic lamina and the absence of medial smooth muscle. **B**, Typical plexiform lesion from a patient with pulmonary arterial hypertension. **C**, Pulmonary arteriole from a patient with pulmonary hypertension from COPD showing cellular intimal proliferation in small muscular arteries. **D**, Pulmonary arteriole from a patient with pulmonary hypertension from COPD showing medial hypertrophy and concentric laminar intimal fibrosis. **E**, Pulmonary arteriole from a patient with pulmonary hypertension from idiopathic pulmonary fibrosis showing vascular intimal fibrosis with luminal obliteration (arrow) in a region of interstitial fibrosis and chronic inflammation. **F**, Pulmonary arteriole from a patient with pulmonary hypertension from IPF showing muscularization of a small pulmonary arteriole. (**A**, Courtesy Dr. Philip Ursell, University of California, San Francisco; **B**, from Leslie KO, Wick MR: *Practical pulmonary pathology: a diagnostic approach: a volume in the pattern recognition series*, ed 2. Philadelphia, 2011, Elsevier, Fig. 11-13A; **C** and **D**, from Carlsen J, Andersen KH, Boesgaard S, et al: Pulmonary arterial lesions in explanted lungs after transplantation correlate with severity of pulmonary hypertension in chronic obstructive pulmonary disease. *J Heart Lung Transplant* 32:347–354, 2013, Fig. 2B and C; **E**, courtesy Dr. Rubin Tudor, Baltimore, MD; **F**, from Colombat M, Mal H, Groussard O, et al: Pulmonary vascular lesions in end-stage idiopathic pulmonary fibrosis: histopathologic study on lung explant specimens and correlations with pulmonary hemodynamics. *Hum Pathol* 38:60–65, 2007, Fig. 1C.)

proportion of vessels. Also, occlusive pathologic changes of pulmonary veins have been observed much more frequently in PH-IPF than in PAH. Ultimately, in patients with IPF, large portions of the pulmonary vascular bed may be destroyed or obliterated from progressive parenchymal fibrosis, inflammation, perivascular fibrosis, and/or thrombotic angiopathy.³⁸⁻⁴⁰

The severity and extent of structural changes correlate variably with the degree of hemodynamic abnormalities seen in PH-LD. A recent study compared the structural changes observed in pulmonary arterioles from patients with COPD with and without PH undergoing transplant. Even without PH, patients with COPD frequently had muscularization and medial thickening of the pulmonary arterioles. Severity of pathologic changes worsened as the hemodynamic abnormalities worsened.⁴¹ In another study of tissue from COPD patients who died during the National Institutes of Health Nocturnal Oxygen Therapy Trial, there was no correlation between the histologic appearance of pulmonary arterioles and PH severity or change in PPA.

Several studies suggest that vascular remodeling in patients with mild COPD without concomitant hypoxemia is a component of early-stage disease as evidenced by increased inflammatory cell density in the adventitia and increased thickness of the intima of pulmonary arteries.^{42,43} Furthermore, endothelial lesions have been shown to be present in cigarette smokers without chronic airflow obstruction.⁴⁴ These findings suggest that, although the pathologic changes in the pulmonary vasculature predominate, other abnormalities appear to contribute to the development of clinically relevant PH.

PATHOGENESIS

The pathogenesis of PH-LD may have multiple mechanisms, including hypoxic pulmonary vasoconstriction, vasoconstrictive neurohormones, and inflammation.

Hypoxic Pulmonary Vasoconstriction

Among all the mechanisms leading to PH in lung disease, the most potent and most important is alveolar hypoxia.⁴⁵ Hypoxic pulmonary vasoconstriction is a normal physiologic response to alveolar hypoxia that was first demonstrated in isolated cat lungs⁴⁶ and subsequently confirmed in healthy human volunteers.⁴⁷ This effect is unique to the pulmonary circulation. Whereas acute hypoxia in the systemic circulation induces vasodilation, acute hypoxia in the pulmonary circulation causes constriction. The constriction of precapillary pulmonary arterioles effectively shunts blood away from poorly ventilated lung units to preserve optimal ventilation-perfusion matching.⁴⁸

Hypoxic pulmonary vasoconstriction results from hypoxia-mediated inhibition of voltage-gated potassium channels in pulmonary artery smooth muscle cells. Hypoxia inhibits the outward flow of potassium through these channels, resulting in depolarization of the membrane and entry of calcium, which causes smooth muscle cell contraction and sustained vasoconstriction.⁴⁸ When activated, this mechanism results in smooth muscle contraction within seconds of exposure to hypoxia. Smooth muscle contraction is augmented by the activity of RhoA and Rho-associated kinase. Hypoxia signals through the G protein

RhoA stimulating Rho-associated kinase to increase phosphorylation of smooth muscle cell myosin light chain and to augment smooth muscle cell contraction, regardless of the level of intracellular calcium.⁴⁸

Even brief periods of hypoxia may result in persistent hemodynamic abnormalities. In six healthy volunteers exposed to 8 hours of hypoxia, there was an increase in PVR, which did not return to normal after 2 hours of normoxia.⁴⁹

Long-term hypoxia-induced structural changes in the pulmonary arterioles were demonstrated in an invasive hemodynamic study of 11 high-altitude natives, which showed that hemodynamics did not normalize even after 2 years at low altitude.⁵⁰ Structural changes in the pulmonary vasculature similar to those observed in COPD and IPF patients are present in the lungs of animals and humans exposed to hypoxia. In an autopsy series of tissues from Andean subjects born and living at high altitude who died without cardiac or pulmonary disease, medial hypertrophy of the pulmonary arteries was seen.²⁸

The degree of increase in PPA secondary to hypoxic pulmonary vasoconstriction varies by species. Pigs, horses, and cows respond with brisk increases in PPA, whereas dogs, yaks, and llamas have a minimal response; humans and rodents have an intermediate response.^{51,52} In addition, the response in humans varies widely among individuals from absent to very intense, with a rise to a \overline{PPA} of 40 mm Hg in 1% to 2% of healthy individuals.^{52,53} One explanation for the observation that some patients with lung disease develop PH whereas others do not is that there are heritable differences in ventilatory sensitivity either to hypoxia and carbon dioxide or in pulmonary vascular reactivity, or both.⁵⁴

Although hypoxia may be a significant contributing factor in the development of PH in chronic lung disease, hypoxia is not the sole factor in generating PH.⁵⁵ This conclusion is supported by the finding that oxygen therapy in patients with lung disease has an inconsistent effect and does not normalize PPA.^{56,57} In addition, hypoxia is not necessary to produce vascular changes; pulmonary vascular structural changes have been observed in patients with mild COPD who do not have hypoxemia, and structural changes seen in the pulmonary vasculature in patients with IPF are more extensive than can be explained by hypoxia alone.⁵⁸

The development of hypercapnia may be one reason why patients with lung disease develop more PH than individuals exposed to environmental hypoxia, such as those living at high altitudes. In patients with PH-COPD, hypoxia is often accompanied by hypoventilation and hypercapnia, causing acidosis, which worsens hypoxic pulmonary vasoconstriction and PVR. This is in contrast to high-altitude dwellers such as healthy Andeans who have chronic hypoxia but generally have hyperventilation with resultant hypocapnia. Despite the presence of hypoxia, the high-altitude dwellers generally do not develop PH, suggesting that hypercapnia and acidemia are important contributing elements.

Neurohormones

Neurohormonal abnormalities and increased sympathetic nervous system activation are observed in patients with

PH-LD and cor pulmonale and contribute to development of hemodynamic abnormalities. Plasma catecholamine levels generally rise in patients with decompensated right heart disease in a manner comparable to that seen in patients with heart failure secondary to primary myocardial disorders. It is clear that increased sympathetic activity is present with decompensation from cor pulmonale, resulting in high plasma levels of circulating catecholamines and stimulation of the renin-angiotensin-aldosterone systems. In the measurements by Anand and associates,⁵⁹ vasopressin actually rose to a higher level in patients with heart failure due to PH-COPD than was seen in comparable patients with heart failure not associated with COPD. Because cardiac output is often normal or may even be increased in decompensated cor pulmonale, it is likely that the decrease in *systemic vascular resistance* (SVR) resulting from both hypercapnia and hypoxia leads to a reflex increase in circulating catecholamines and other neural hormones. Central sympathetic stimulation may also be encouraged by the direct effect of the increased PCO₂ on the central nervous system.

Angiotensin. Angiotensin II is a potent vasoconstrictor of the pulmonary vascular bed. The pulmonary vasculature appears to be even more sensitive to the vasoconstrictor effects of angiotensin II than is the systemic vascular bed. This is noteworthy because increased circulating levels of angiotensin II and aldosterone are found in patients with cor pulmonale secondary to COPD who have hypoxia and hypercapnia.⁶⁰ Activation of the renin-angiotensin-aldosterone systems, together with hypoxemia, is probably an underlying pathophysiologic mechanism responsible for the elevation in PVR that is observed in patients with decompensated cor pulmonale.

Angiotensin induces a dose-response increase in PVR in normal subjects.⁶¹ Angiotensin II inhibitors have been shown to lower PVR and to be beneficial in patients with cor pulmonale, especially in patients with IPF. Angiotensin II inhibitors have also been demonstrated to improve survival in patients with systolic heart failure caused by both coronary disease and idiopathic dilated cardiomyopathy. It is encouraging to note that the angiotensin-converting enzyme inhibitor lisinopril has been demonstrated experimentally to attenuate the pulmonary pressor response to hypoxic pulmonary vasoconstriction in healthy human volunteers.⁶² In addition, angiotensin II receptor blockade has been shown to produce a similar effect in hypoxic pulmonary vasoconstriction in humans.⁶³ However, studies performed to date have not clarified a role for angiotensin-converting enzyme inhibitors or angiotensin II receptor antagonists in the treatment of cor pulmonale.

Endothelin. *Endothelin-1* (ET1) is a 21-amino acid peptide secreted by vascular endothelial cells in response to stimuli, including pulsatile stretch, sheer stress, neurohormones, cytokines, growth factors, and thrombin. The secretion of ET1 has been shown to be increased by hypoxemia in humans. The effects of ET1 are mediated by both *endothelin A* (ET_A) and *endothelin B* (ET_B) receptors. ET_A is localized on vascular smooth muscle cells, and ET_B is expressed on vascular smooth muscle cells, endothelial cells, and fibroblasts. The effects of ET1 include vasoconstriction, hyperplasia,

hypertrophy, fibrosis, and increased vascular permeability. Activation of ET_B receptors on endothelial cells mediates release of prostacyclin (prostaglandin I₂) and *nitric oxide* (NO), which exert vasodilatory and antiproliferative effects while also inhibiting ET1 production by endothelial cells. Furthermore, the pulmonary endothelial ET_B receptors are responsible for the pulmonary clearance of up to 50% of circulating ET1.⁶⁴ Endothelin-1 is a potent vasoconstrictor and mitogen, and NO is a pulmonary vasodilator and inhibitor of fibrosis.

Increased ET1 production has been described in patients with PAH, and both increased ET1 levels and increased expression of receptors have been shown to be present in plexiform lesions of the lung in patients with PAH.^{64,65} Furthermore, the high plasma levels of ET1 correlate with disease severity and adverse prognosis.⁶⁵⁻⁶⁹ ET1 concentration is also elevated in the sputum and urine of patients with COPD compared to normal subjects; moreover, urinary levels increase further during COPD exacerbations.^{70,71} In addition, plasma ET1 levels have been shown to be increased in subjects who exhibit worsening oxygen saturation with exercise or at night.^{72,73} In another study, patients with PH-COPD were shown to have elevated transpulmonary ET1 levels.⁷⁴ Increased plasma levels and lung tissue expression of ET1 have also been identified in patients with IPF with or without PH.⁷⁵

Inflammation

Inflammation has been hypothesized to play a significant role in the development of the vascular changes seen in PH-LD because increased markers of inflammation and inflammatory mediators have been observed in patients with PH-LD. However, the exact role of inflammation in PH-LD remains controversial.⁷⁶ Increased numbers of CD8⁺ T lymphocytes have been observed in the walls of pulmonary vessels of patients with COPD. Furthermore, the presence of these cells was correlated to the enlargement of the intimal layer.⁴² Similar findings have been observed in the lungs of smokers without COPD or PH, suggesting that cigarette smoke might induce these inflammatory markers. In another study, elevated serum levels of inflammatory cytokines, including C-reactive protein and tumor necrosis factor- α , were seen in patients with PH-COPD.⁷⁷ In patients with PH-IPF, elevated levels of multiple inflammatory mediators have been seen, including thromboxane A₂, tumor necrosis factor- α , platelet-derived growth factor, transforming growth factor- β , and fibroblast growth factor.^{56,78,79} Studies of gene expression suggest that inflammatory mediators are overexpressed in patients with PH-IPF.⁸⁰ Further studies are needed to determine the causal nature of these changes and whether antagonizing inflammation could be of therapeutic value.

RIGHT VENTRICLE

The healthy *right ventricle* (RV) is a thin-walled structure with a complex shape that appears crescentic when viewed in cross section and triangular when viewed from the side (Fig. 59-5). Superficial RV muscle fibers are arranged circumferentially, and deep fibers are arranged longitudinally from apex to base so that the RV contracts by three separate mechanisms: (1) shortening along the long axis, drawing

Figure 59-5 Appearance of the right ventricle in pulmonary hypertension. **A**, A transverse section through a normal heart illustrates a crescent-shaped right ventricular cavity, thin right ventricular free wall (arrows) and round left ventricular cavity (line). **B**, Transverse section of a heart from a patient who had severe pulmonary hypertension showing dilation of the right ventricular cavity, giving the heart a more spherical shape than the normal heart. Also seen is thickening of the right ventricular free wall (arrows) and flattening of the interventricular septum (line). (Scale below in centimeters). LV, left ventricle; RV, right ventricle. (Courtesy Dr. Philip Ursell, University of California, San Francisco.)

the base to the apex; (2) inward movement of the free wall, which produces a bellows effect with the RV squeezing against the thick wall of the left ventricle (LV); and (3) traction on the RV free wall at the point of attachment with the LV.⁸¹ Because the RV is in series with the LV, cardiac output from both chambers is equal. The RV, however, is coupled to the normally low-pressure and compliant pulmonary arterial tree so that RV stroke work is significantly less and the RV functions as a volume pump as opposed to a pressure pump like the LV. Under normal physiologic conditions, the RV handles increased volume easily by increasing RV stroke volume. Regulation of RV contractility in the healthy RV is similar to the LV and is dependent on factors such as heart rate, the Frank-Starling mechanism (stroke volume increases as preload increases), and autonomic neural input.⁸¹⁻⁸³

The pattern of development of RV structural and functional abnormalities is similar in patients with PH-LD and PAH and is secondary to the increased afterload on the RV that results from the increase in PVR (see Fig. 59-5). The changes in the RV from pressure overload are distinct from

changes in the RV secondary to volume overload as from conditions such as severe tricuspid regurgitation. RV afterload generally increases slowly in patients with chronic lung disease as PPA and PVR rise, leading to progressive RV hypertrophy, which minimizes wall stress. The RV eventually dilates so that the normal crescent shape of the RV is progressively transformed into a more spherical structure that is better able to generate an increased stroke work (see Fig. 59-5). RV dilation and wall thinning result in increased RV wall stress that, along with increased heart rate, leads to further increases in myocardial oxygen consumption, decreased myocardial perfusion, and RV ischemia. As the RV dilates, severe tricuspid regurgitation may develop, further compromising RV cardiac output and LV filling. RV dilation in the setting of an intact pericardium compromises LV filling by shifting the interventricular septum toward the LV and reducing LV filling and cardiac output.⁶³ Nevertheless, several studies of end-diastolic pressure-volume relationships suggested well-preserved RV contractility in patients with COPD.⁸⁴ Only the additional presence of acidemia or infection precipitates RV failure. When chronic hypercapnia with acidosis is present in patients with alveolar hypoventilation, the ability of the RV to increase its work appears to be significantly impaired, and RV end-diastolic pressure increases.

There may be subtle changes before elevations in PPA can be detected. For example, even before the development of significant elevations in PPA, RV hypertrophy and pathologic remodeling has been observed in patients with chronic lung disease. This was studied by echocardiographic and invasive hemodynamic evaluation of the RV in a group of 98 patients with stable moderate to severe COPD and no known heart disease.⁸⁵ Compared to 34 healthy controls, patients with COPD but without PH had increased RV wall thickness, RV size, and outflow tract dimension, as well as functional abnormalities assessed by myocardial performance index, RV isovolumic acceleration, and RV strain. In another study of patients with COPD, pulmonary artery compliance was reduced before PVR was significantly elevated, suggesting that decreases in compliance may be an early marker of hemodynamic compromise. In patients with lung disease, it is likely that early destruction of the pulmonary vascular bed, though not sufficient to increase PVR, significantly reduces pulmonary artery compliance and contributes to early increases in RV afterload and subsequent RV hypertrophy.⁸⁶

RV myocardial ischemia may also play a role in RV failure. RV coronary perfusion decreases with the increase in wall thickness even as the hypertrophy and dilation of the RV produces a significant increase in RV myocardial oxygen consumption. RV coronary perfusion also decreases with the increase in end-diastolic pressure as RV stiffness increases during diastole. Taken together, these factors result in an imbalance between RV myocardial oxygen demand and supply.

This impairment of myocardial contractility in the presence of hypercapnia probably plays a significant role in producing decompensated pulmonary heart disease in response to acute increases in arterial PCO₂ associated with exacerbations of COPD and accompanying decreases in alveolar ventilation. The development of RV volume overload with ventricular dilation results in a decreased ejection fraction,

because stroke volume tends to be maintained close to the normal range in decompensated cor pulmonale.⁸⁷ With exercise, patients with COPD significantly raise their RV afterload, which causes further increases in RV end-diastolic volume and decreases in ejection fraction. It is likely that this deterioration in hemodynamic performance with exercise is a major factor limiting the ability of such patients to exercise normally.

In the presence of RV failure and elevated central venous pressure, the patient can stand up without a decrease in RV end-diastolic volume or stroke volume; consequently, the heart rate does not change. This lack of postural reflex compensation is attributable to failure of any incremental gravitational pooling of blood in the venous system, because of increased plasma volume, increased tissue pressure from edema with decreasing venous dispensability, and increased venomotor tone.⁸⁸

LEFT VENTRICLE

Although LV ejection performance is unimpaired, cardiac catheterization studies have revealed abnormal LV end-diastolic pressure-volume relationships.⁸⁹ Echocardiographic studies have also shown progressive impairment of LV diastolic function that correlates with the severity of PH.⁹⁰ It is likely that this results, in large part, from bulging of the interventricular septum from the hypertrophied and dilated RV into the cavity of the LV, and ventricular interdependence exerted by pericardial constraint.^{63,91} As a result, LV diastolic geometry becomes distorted,⁹² and filling characteristics may be altered so that a higher filling pressure is required to accomplish the same end-diastolic fiber stretch needed for a given stroke work, in accordance with the Frank-Starling mechanism. With severe RV failure and marked elevation in right atrial pressure, coronary venous pressure increases significantly; this increase in coronary venous pressure can result in an increase in LV wall dimension limiting LV distensibility. This mechanism leading to reduced LV preload appears to act independently of diastolic ventricular interaction caused by RV enlargement as previously described.⁹³

LUNG MECHANICS

In healthy individuals, ordinary inspiration causes a small reduction of 3 to 5 cm H₂O in pleural pressure that is adequate to generate a normal tidal volume with only a small transmission of intrathoracic pressure affecting the heart and pulmonary vasculature. Increased stiffness of the chest wall or the lung parenchyma means that patients with obesity or obstructive or restrictive lung diseases must generate more negative pleural pressures to achieve an adequate tidal volume. Additionally, patients with COPD often have lung hyperinflation secondary to airflow obstruction, loss of elastic lung parenchyma, or dynamic hyperinflation. These abnormalities in pulmonary mechanics may contribute significantly to the pathophysiologic features of PH.

Lung hyperinflation affects RV function through changes in RV preload and afterload. Increased lung volumes in diseases such as COPD can passively compress alveolar vessels directly, increasing PVR and RV afterload,⁹⁴ and in some

cases, hyperexpanded lungs may even directly compress the heart with negative effects on cardiac performance.⁹⁵ Exaggerated swings in intrathoracic pressure such as those seen in patients with OSA can result in increased right-sided venous return, which causes acute RV enlargement and in turn impedes LV filling and cardiac output. At the same time, reductions in intrathoracic pressure increase LV afterload, which may be transmitted backwards and result in transient increases in PPA.⁹⁶ In patients with acute bronchospasm, echocardiographic studies have shown acute inspiratory RV dilation and simultaneous reduction in LV cavity size that reverse during expiration, resulting in increased PVR from hyperinflation and increased RV wall tension from exaggerated negative pleural pressure. Importantly, the clinical significance of these effects may depend largely on the cardiovascular reserve of the specific patient.⁹⁴

CLINICAL PRESENTATION

There are many causes of PH, as noted in [Table 59-1](#). At times the underlying cause may be difficult to establish, and often the cause of PH is multifactorial. In one study of 998 patients with COPD undergoing right heart catheterization, 27 were found to have PPA greater than or equal to 40 mm Hg; after complete evaluation, 16 (59%) were found to have another cause of PH, including administration of appetite suppressants, left ventricular dysfunction, chronic thromboembolic PH, collagen vascular disease, portal hypertension, and OSA.⁶ When evaluating a patient with a new diagnosis of PH, an exhaustive evaluation is required to identify all possible causes of increased PPA.⁹⁷ The prognosis and treatment of PH vary dramatically with the cause so that the significance of PH and optimal treatment require a complete and accurate understanding of the underlying cause or causes.

SYMPTOMS AND SIGNS

The first step in the evaluation is a comprehensive history and physical examination to identify any conditions that might cause PH. Specifically the patients should be questioned regarding use of appetite suppressants or other toxic substances, a history of liver disease and portal hypertension and diagnosis or symptoms of systemic lupus erythematosus, scleroderma, or other collagen vascular disease, or a history of venous thromboembolism. In patients already diagnosed with lung disease, it is important that the lung disease be well characterized and that definitive diagnostic studies have been performed and are reviewed. Studies to exclude daytime hypoxemia with exercise and nocturnal hypoxemia from OSA should be performed. Left-sided heart disease is the most common cause of PH⁴ and must be identified if it is contributing to PH. Although echocardiography is useful to detect LV systolic dysfunction and valvular abnormalities that may cause PH, heart failure with preserved ejection fraction (formerly called diastolic heart failure) can be missed and may be detected only during comprehensive invasive hemodynamic assessment.^{7,10}

Mild PH-LD reflected in small chronic elevations in RV pressure generally causes minimal, if any, clinical, radiologic, or electrocardiographic findings. When moderate or

severe PH-LD develops ($\overline{\text{PPA}} > 40$ mm Hg), symptoms are often similar to those associated with the underlying pulmonary disease. Most commonly, these are dyspnea on exertion, chronic cough productive of mucoid sputum, wheezing, and occasional cyanosis. Clubbing of the fingers may be present. In addition to exertional dyspnea and fatigue, some patients experience dizziness or exertional syncope, attributable to the inability to increase cardiac output during exercise in the face of a marked increase in PVR. Furthermore, these patients may have chest pain owing to RV ischemia or stretching of the main pulmonary artery.

When resting PPA is sufficiently elevated, patients may eventually reach a point at which the RV cannot meet the need for increased stroke work without a significant increase in right heart filling pressures. The resultant increase in central venous pressure is associated with developing symptoms of right-sided heart failure, such as peripheral edema, right upper quadrant discomfort, nocturia, and easy fatigability.

On examination, the patient is often cyanotic and sitting upright with tachypnea, with prominent use of the accessory muscles of breathing, and arms extended holding on to the edges of the mattress. In COPD, pulsus paradoxus may be present, the chest is often hyperinflated, and otherwise mild wheezing may be audible. Sinus tachycardia is often present; however, atrial and ventricular arrhythmias are also common.⁹⁸ Evidence of fluid retention may include dependent edema and ascites. The liver may be enlarged and tender to palpation and may be pulsatile, reflecting the presence of severe tricuspid regurgitation. Similarly, the neck veins may be distended and, when tricuspid regurgitation is present, show a large *c-v* wave with rapid *y* descent. Signs of volume overload secondary to RV dysfunction must be distinguished from sympathetically mediated renal salt and water retention without RV dysfunction, which can also develop in patients with lung disease.⁹⁹

On examination of the chest, there may be a left parasternal systolic lift, owing to the overactivity of the enlarged RV, and a thud felt over the pulmonary area as the pulmonary valve closes. The heart sounds are often difficult to hear if the patient has underlying COPD. The pulmonic component of the *second heart sound* (*S*₂) may be accentuated and be heard earlier than usual, so the normal splitting may be abolished and a single loud *S*₂ heard. Normally not heard at the apex, the pulmonic component of *S*₂ may be clearly heard. A high-pitched systolic ejection click may be heard in the second and third left intercostal spaces next to the sternum. It is often followed by a soft, localized systolic ejection murmur produced by ejection of the stroke volume into a dilated pulmonary artery. An *S*₃ gallop arising from the right side of the heart may be heard in the fourth and fifth interspaces immediately to the left of the sternum or even next to the xiphoid process. A presystolic *S*₄ gallop may also be heard, reflecting the increased forcible contraction of the right atrium with expulsion of blood into the hypertrophied and dilated RV. Often tricuspid regurgitation is present, and this results in a prominent blowing pansystolic murmur with respiratory variation in the same location. When prominent PH is present, a diastolic murmur of pulmonic valve regurgitation may be heard; this murmur, known as a Graham Steell murmur, is a soft, blowing decrescendo

Figure 59-6 Electrocardiogram from a patient with pulmonary hypertension. Findings include a prominent “p pulmonale” and increased R wave voltage in the anterior precordial leads suggestive of right atrial and right ventricular abnormalities.

diastolic murmur, usually well localized to the second and third left intercostal spaces next to the sternum.

ELECTROCARDIOGRAPHY

Characteristically, the P wave of the electrocardiogram has a “p pulmonale” pattern with right-axis deviation resulting in an increase in its amplitude in leads II, III, and aVF to more than 2.5 mm (Fig. 59-6). The P wave may also be tall in the right precordial leads. The QRS vector in the frontal plane often shifts to the right in cor pulmonale, and a low-voltage QRS complex is common if lung hyperinflation is present. Prominent S waves are seen in leads I, II, and III. An incomplete right bundle-branch block pattern is also frequently observed. When PH is moderate or severe, the more classic findings of RV hypertrophy may dominate the electrocardiogram, including tall R waves in *V*₁ with an R/S ratio of more than 1, and a prominent S wave in *V*₅ and *V*₆ with an R/S ratio of less than 1. The presence of electrocardiographic evidence of cor pulmonale in patients with COPD is a poor prognostic sign.¹⁰⁰

CHEST RADIOGRAPHY

In addition to radiographic findings of the underlying lung disease, the chest radiograph should be evaluated for features of right heart failure and pulmonary vascular abnormalities. There may be enlargement of the main pulmonary artery as well as enlargement of the right and left descending pulmonary arteries. Abrupt tapering of the peripheral vessels may result in disproportionately large central pulmonary arteries and attenuated distal vessels. A right descending pulmonary artery with a diameter greater than 16 mm suggests PH.¹⁰¹ Enlargement of the RV may be seen on the lateral projection of the chest radiograph as a reduced retrosternal space. If hyperinflation of the lungs is present, the overall diameter of the cardiac silhouette may not be increased, although the heart may have a globular appearance.

The chest radiograph should be carefully evaluated for evidence of left heart failure. Pleural effusions are seldom seen in patients presenting with PH-LD and right heart failure unless coexisting left ventricular dysfunction and failure are also present. Radiographic findings of pulmonary edema also point to left heart failure as a likely cause of PH. Additionally, a diagnosis of pulmonary

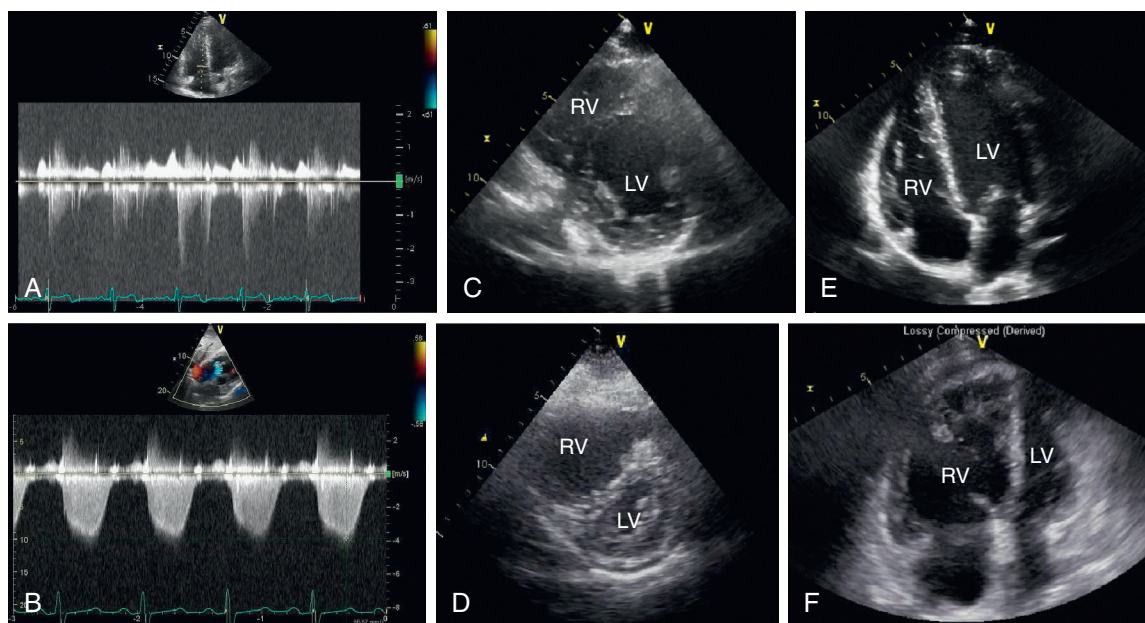

Figure 59-7 Echocardiography in the evaluation of pulmonary hypertension. **A**, Poor-quality tricuspid regurgitant jet from which the pulmonary artery systolic pressure (PASP) cannot be estimated. **B**, Good-quality tricuspid regurgitant jet that is useful for estimating the PASP. Even when a good-quality jet can be obtained, the echocardiographic assessment of PASP may be inaccurate. **C**, Short-axis echocardiographic image of a normal heart demonstrating a rounded left ventricle (LV) and normal-appearing right ventricle (RV). **D**, Short-axis echocardiographic image from a patient with pulmonary hypertension demonstrating flattening of the interventricular septum and a D-shaped LV during systole and a large RV. **E**, Apical four-chamber echocardiographic view of a normal heart demonstrating a normal-sized RV and LV. **F**, Apical four-chamber echocardiographic view from a patient with pulmonary hypertension demonstrating a markedly enlarged RV with a small, compressed LV. There is also enlargement of the right atrium. (See Videos 59-1A and B and 59-2A and B.)

veno-occlusive disease should be considered in patients with PH and pleural effusions.

ECHOCARDIOGRAPHY

Echocardiography is widely available, inexpensive, uses no radiation, and can be performed serially, making it a useful tool for estimating PPA and evaluating RV structure and function (Fig. 59-7, Videos 59-1A and B and 59-2A and B). An echocardiogram is often the earliest test that suggests a diagnosis of PH and is important in assisting the clinician in eliminating various nonpulmonary causes of PH, such as ischemic or nonischemic LV systolic dysfunction, aortic or mitral valve disease, and congenital heart disease with left-to-right shunt.

Echocardiography is often used to estimate the PASP, which can be determined in 36% to 86% of patients with PH-LD by taking advantage of the presence of tricuspid regurgitation and using continuous-wave Doppler recording to obtain the tricuspid regurgitant jet velocity.^{9,102} First, the pressure gradient across the tricuspid valve between the right atrium and ventricle is calculated using the modified Bernoulli equation ($\text{pressure gradient} = 4v^2$), where v is the tricuspid regurgitant jet velocity; this value is then added to the right atrial pressure—estimated by the size and collapsibility of the inferior vena cava—to obtain an estimate of the RV systolic pressure, which in the absence of pulmonary valve stenosis equals PASP.¹⁰³

Echocardiographic estimates of PASP are subject to important limitations, especially among patients with parenchymal lung disease and obese patients. The presence

of hyperinflation of the lungs impairs the transmission of ultrasound and can result in suboptimal image quality so that an adequate tricuspid regurgitant jet cannot be measured; in one large series of patients with advanced lung disease, a satisfactory PASP could be estimated in only 44% of patients.¹⁰⁴ The sensitivity and specificity of Doppler echocardiography to predict the presence of PH range from 0.79 to 1.0 and from 0.6 to 0.98, respectively.¹⁰² However, when compared to invasive assessment, the echocardiographic estimate of PASP shows only moderate correlation and is often inaccurate.¹⁰⁴⁻¹⁰⁶ Therefore, in patients with symptoms or clinical signs that are concerning for PH, right heart catheterization should be considered even if the echocardiographically estimated PASP is normal.

Structural and functional information about the size of the right atrium and RV is probably the most valuable information that can be obtained from the echocardiogram.¹⁰⁷ Right atrial pressure can be assessed by evaluating the size of the inferior vena cava and changes in its size with respiration. Flattening or leftward shift of the interventricular septum during systole and septal flattening during diastole both suggest RV volume overload. Assessment of RV function by echocardiography is challenging because the RV is often difficult to image and image quality may be inadequate to perform objective measurements. In a study of 32 patients with advanced lung disease, Schenk and colleagues¹⁰⁸ found that, among various echocardiographic parameters, RV end-diastolic area and fractional area change from the apical four-chamber view correlated best with the gold standard *magnetic resonance imaging* (MRI)–derived RV volume and ejection fraction, respectively.

Figure 59-8 Chest CT scan in a patient with chronic lung disease demonstrating enlargement of the main pulmonary artery. Enlargement of the main pulmonary artery suggests the diagnosis of pulmonary hypertension. $D = 36.4$ mm, whereas the mean main pulmonary artery diameter in healthy controls is 25.1 ± 2.8 mm.^{110a}

Doppler-derived indices of RV function, the tricuspid annular plane excursion¹⁰⁹ and RV myocardial performance index,¹¹⁰ have both been shown to have prognostic value in patients with idiopathic PAH and are being studied in other groups of PH.

COMPUTED TOMOGRAPHY

Chest *computed tomography* (CT) is often used to visualize the pulmonary parenchyma in patients with respiratory disease. Using this imaging modality, the size of the pulmonary artery can be measured, and, in patients with moderate to severe PH, enlargement of the main pulmonary artery or an increased diameter of the pulmonary artery (>29 mm) may be documented (Fig. 59-8). This finding may have prognostic significance, and, in a study of 3464 patients with COPD, a pulmonary artery-to-aorta ratio higher than 1 was associated with future severe COPD exacerbations (odds ratio, 3.44; $P < 0.001$).¹¹¹ However, in a study of 65 patients with advanced IPF, main pulmonary artery diameter on chest CT failed to differentiate between those who did or did not have PH diagnosed by right heart catheterization.¹¹² Other findings such as dilated right-sided heart chambers on contrast-enhanced CT imaging are suggestive but not diagnostic of cor pulmonale in patients with severe parenchymal lung abnormalities.

MAGNETIC RESONANCE IMAGING

Currently MRI is the most accurate method for assessing characteristics of the RV, including its volume, mass, and systolic function. Additionally, phase-contrast MRI has the capability to calculate accurate flow characteristics, including cardiac output, valvular regurgitant fraction, and both right- and left-sided shunt fractions. MRI has significant advantages over echocardiography in that it can image in any desired imaging plane, has a large field of view, and is not limited by acoustic windows. Although high cost, relatively long image acquisition time, and lack of widespread availability limit its use compared with echocardiography, cardiac MRI is increasingly being used as the standard method for evaluating RV structure and function in patients with PH.^{113,114}

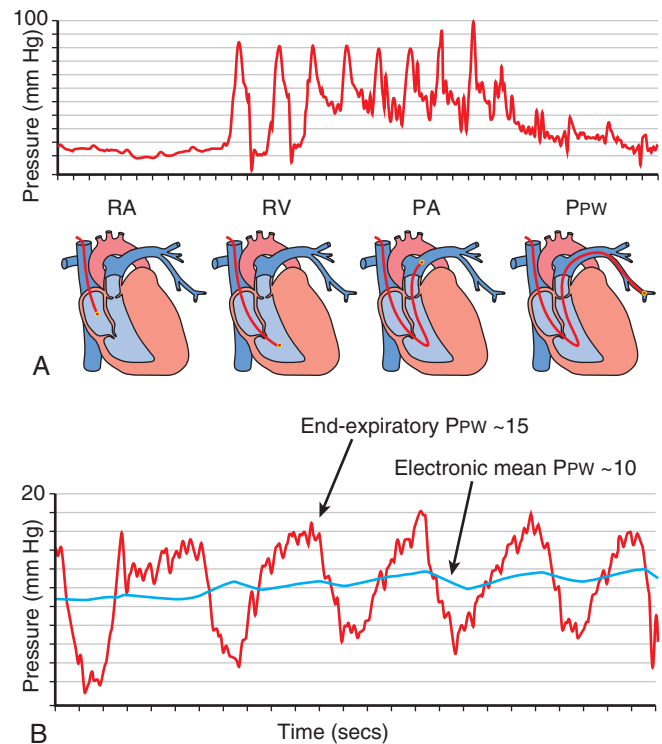

Figure 59-9 Tracings from right heart catheterization in patients with pulmonary hypertension. **A**, Waveforms that are obtained as the catheter passes from the right atrium (RA) through the right ventricle (RV), pulmonary artery (PA), and into the pulmonary capillary wedge position in a patient with pulmonary hypertension. Notable findings include the markedly elevated pulmonary artery pressure and the normal pulmonary capillary wedge pressure (PPW). **B**, PPW tracing from another patient with chronic lung disease demonstrating marked respiratory variation in the wedge pressure. Abrupt rise in pressure in some respiratory cycles at the end of expiration likely represents forceful expiration, which is sometimes seen in patients with lung disease. It is important to identify and measure the pressure at end-expiration correctly. Use of the computer-measured mean wedge pressure is misleading because the mean wedge pressure is calculated to be normal, whereas the actual end-expiratory wedge pressure is elevated, suggesting a diagnosis of pulmonary hypertension from left heart disease.

RIGHT HEART CATHETERIZATION

In patients with PH, right heart catheterization is required to confirm the diagnosis and is the gold standard test to measure PPA. Besides measuring PPA, right atrial pressure, cardiac output, and left-sided filling pressures, wedge pressure (Fig. 59-9) should be determined. Using these data, values for PVR, SVR and PVR-to-SVR ratio can be calculated. The presence of a congenital systemic-to-pulmonary shunt can be assessed during right heart catheterization by performing an oxygen saturation assessment across the right-sided heart chambers. If echocardiographic imaging is not adequate, hemodynamic assessment of right-sided heart valves can also be performed during right heart catheterization. Pulmonary angiography may be performed if there is a concern for chronic thromboembolic PH.¹¹⁵

It is important that right heart catheterization be performed in centers with experience evaluating patients with PH. Attention to technical aspects of the procedure is needed to ensure that good quality data are obtained; it is important that the transducer is properly leveled and zeroed

and that all measurements are made at end-expiration, when gas flow is minimal and transthoracic pressure is zero, to assess hemodynamics without respiratory influence.¹¹⁶ Improper performance of the hemodynamic assessment may lead to incorrect diagnosis of the underlying cause of PH.¹¹⁷ The correct timing of hemodynamic measurements may be particularly difficult in patients with parenchymal lung disease who may be breathing forcefully and increase their intrathoracic pressure at the end of expiration. Because left-sided heart abnormalities and increased filling pressures are common in patients with lung disease^{118,119} and can be treated with diuretics, it is critical that wedge pressure be properly measured so as not to miss a contribution of elevated LV filling pressures to PH. A blood sample drawn from the right heart catheter in the wedge position showing an oxygen saturation similar to the systemic arterial saturation is useful to confirm a correctly measured wedge pressure. Uncertainty about the validity of the measured wedge pressure may be resolved by direct measurement of left ventricular end-diastolic pressure. Assessments of cardiac output in patients with PH-LD should be made using both the Fick and thermodilution cardiac output methods.¹¹³ Challenge with vasodilators should not be routinely performed in the evaluation of patients with PH-LD (see “Treatment” section).

The 2013 guidelines provide recommendations for terminology and classification of patients with lung disease based on invasive hemodynamic assessment.¹²⁰ These guidelines specifically recommend against the use of the term *out of proportion PH*, which has been used frequently in the past. Patients are instead placed in one of three possible categories: (1) lung disease without PH ($\overline{PPA} < 25$ mm Hg), (2) lung disease with PH ($\overline{PPA} \geq 25$ mm Hg), and (3) lung disease with severe PH ($\overline{PPA} \geq 35$ mm Hg **or** $\overline{PPA} \geq 25$ mm Hg and cardiac index < 2.0 L/min/m²).

B-TYPE NATRIURETIC PEPTIDES

Measurement of *B-type natriuretic peptides* (BNPs) may be useful in the assessment of patients with lung disease and possible PH if there are no other reasons for elevated BNP values. In one study, plasma BNP was measured in 176 consecutive patients with a variety of pulmonary diseases¹²¹; elevated BNP levels identified PH (defined as $PASP > 35$ mm Hg) with a sensitivity of 0.85 and a specificity of 0.88 and predicted mortality. In both univariate and multivariate analysis, BNP was found to be a risk factor for death independent of pulmonary function impairment or hypoxemia.¹²¹

TREATMENT

In the vast majority of patients with PH-LD, optimal treatment of the underlying lung disease according to established guidelines is by far the best approach to managing PH. Comorbidities that worsen PH, such as left-sided heart disease, valvular disease, pulmonary emboli, and sleep-disordered breathing should also be sought and aggressively treated. Because PH portends a poor prognosis in patients with lung disease, timely referral for lung transplant evaluation is imperative. Although it may be tempt-

ing to treat patients who have PH-LD with therapies proven useful in group 1 PAH, these treatments have not been shown to be useful, and some have been harmful in patients with lung disease. Updated guidelines strongly discourage using treatments for PAH in patients with PH-LD.^{120,122} We recommend consultation at a center of excellence with experience in the evaluation and management of PH-LD disease before initiation of PAH-specific therapy; if warranted, patients should be enrolled in prospective treatment trials.

TREATMENTS USEFUL IN ALL PATIENTS WITH PH-LD

In patients with PH-LD, optimal treatment directed at the specific underlying pulmonary disorder is mandatory and is the subject of most of this textbook. The overall therapeutic strategies for PH-LD and RV failure are shown in Table 59-2.^{123,124}

Lifestyle Modifications

In the management of PH-LD, diet and lifestyle modifications are crucially important. Smoking cessation is the most important of all preventive lifestyle interventions, especially considering the possible direct harmful effect of cigarette smoke on the pulmonary vasculature.⁴³ Other safeguards consist of sodium restriction, weight loss, and exercise training to improve functional performance. Structured rehabilitation programs and breathing training have been shown to be useful.^{63,125} Patients with severe PH or RV dysfunction, especially those with a history of syncope, should avoid overexertion, pregnancy, and high altitudes (>1220 m [4000 feet]).

Table 59-2 Therapeutic Strategies for Pulmonary Hypertension Due to Lung Disease

FOR ALL PATIENTS

- Treatment of underlying lung disease
- Lifestyle modification
- Smoking cessation
- Sodium restriction
- Weight loss
- Judicious exercise training
- Structured rehabilitation and breathing training programs
- Avoidance of overexertion
- Avoidance of pregnancy
- Avoidance of high altitudes
- Supplemental oxygen
- Diuretics
- Treatment of sleep-disordered breathing and alveolar hypoventilation disorders (CPAP, BiPAP, surgery)
- Lung transplantation

FOR SELECTED PATIENTS

- Anticoagulation
- Digoxin
- Lung volume reduction surgery
- Phlebotomy
- Iron supplementation
- PAH-specific therapies (use discouraged except in highly selected circumstances and when managed by a pulmonary hypertension referral center)

BPAP, bilevel positive airway pressure; CPAP, continuous positive airway pressure; PAH, pulmonary arterial hypertension.

Oxygen

Alveolar hypoxia may make a major contribution to the genesis of PH-LD, and aggressive treatment with supplemental oxygen to correct hypoxia is central to optimal treatment. Controlled trials evaluating long-term oxygen administration in COPD showed improvement in survival. Oxygen administration may have beneficial effects on hemodynamics,^{126,127} RV function,¹²⁸ and exercise tolerance.

The effects of oxygen supplementation in PH-LD have been studied in two major randomized trials. First, in the British Medical Research Council evaluation of long-term home oxygen in chronic hypoxic cor pulmonale, long-term oxygen administration for at least 15 hr/day lessened mortality and appeared to prevent further increases in PPA, compared with no oxygen administration in control patients.¹²⁹ Second, in a National Institutes of Health-sponsored study in the United States, continuous oxygen therapy was better than nocturnal therapy alone; furthermore, continuous oxygen lessened mortality rate at 2 years¹³⁰ and decreased PVR in comparison with the group receiving only nocturnal therapy. These findings were confirmed in two more recent studies both showing stabilization of PPA with long-term oxygen therapy.^{131,132} There are other beneficial effects of oxygen therapy, including relief of renal vasoconstriction and improvement in oxygen delivery to critical organs such as the heart and brain.¹³³

Based on the results of these studies, it is clear that hypoxemic patients with COPD should receive supplemental oxygen therapy. Additionally, there is evidence that oxygen improves functional class and symptoms in patients with IPF so that in these patients maintenance of arterial oxygen saturation at or slightly over 90% at rest and especially with activity has been recommended.⁷⁹ It must be remembered, however, that the acute administration of inordinate concentrations of oxygen to a patient can have adverse effects on breathing and carbon dioxide removal, particularly in patients already hypoventilating with evidence of hypercapnia. Patients given oxygen need to be observed closely when they are initially being instructed on the use of this therapy to ensure that arterial oxygen saturation actually rises, but not too high: flow rates of 1 to 3 L/min generally suffice. Further information about the long-term use of oxygen in pulmonary rehabilitation is provided in Chapter 105.

Diuretics

Diuretic therapy to optimize volume status alleviates dyspnea, hepatic congestion, and peripheral edema. Decompression of the RV with diuretics may also improve RV performance by reducing preload and wall stress. Judicious diuresis may reduce intrapericardial pressure and potentially attenuate interventricular septal shift toward the LV, resulting in increased LV filling and improved systemic cardiac output.

Treatment of Sleep-Disordered Breathing

Sleep-disordered breathing is common in patients with COPD and can contribute to nocturnal hypoxemia and hypercapnia, leading to increased pulmonary vasoconstriction. As described in Chapter 88, continuous positive airway

pressure exerts its beneficial effects by maintaining patency of both upper and lower airways and improving gas exchange. Patients diagnosed with OSA should be treated with continuous positive airway pressure and supplemental oxygen as required; in patients with OSA, continuous positive airway pressure is associated with improved ventricular function and survival and reduced hematocrit level.¹³⁴⁻¹³⁶ In patients who have nocturnal hypoxemia without evidence of OSA, supplemental oxygen alone may be adequate.

Lung Transplantation

There is a clear role for lung transplantation in patients with PH-LD.¹³⁷ Because development of PH and right heart failure in patients with lung disease portends a poor prognosis and there are no effective medical therapies, timely referral for evaluation for lung transplantation is critical. Early referral to a transplantation center is preferred so that candidacy can be determined and barriers to transplantation can be identified and addressed. Recovery of RV function and good long-term prognosis have been demonstrated in patients following both single- and double-lung transplant for PH.^{138,139}

There is conflicting evidence regarding the effects of pretransplantation hemodynamics on posttransplantation mortality in patients with PH-LD. A retrospective study of 830 patients treated with lung transplant for IPF found that 90-day posttransplantation mortality increased with increasing pretransplant PPA.¹⁴⁰ Another retrospective study showed that, in COPD patients undergoing lung transplantation, a preoperative echo-estimated PASP of 45 mm Hg or higher was associated with increased intensive care unit length of stay and duration of mechanical ventilation but was not associated with reduced survival.¹⁴¹ The degree of pretransplantation RV dysfunction is potentially more important than PPA and may be considered by the transplantation team when determining risk and transplantation candidacy and the optimal surgical approach (single or double lung, on pump or off pump).¹⁴² In patients with more advanced RV dysfunction, use of mechanical support such as extracorporeal membrane oxygenation during the perioperative period has been used to provide hemodynamic support and permit transplantation in patients with right heart failure^{143,144} (see Chapter 103).

TREATMENTS THAT MAY BE CONSIDERED IN SELECTED PATIENTS

Anticoagulation

In patients with group 1 PAH, oral anticoagulation is considered the standard of care¹⁴⁵ based on one retrospective and one prospective trial that showed a mortality benefit.^{146,147} In patients with PH-LD, on the other hand, there are currently no data regarding the utility of treatment with anticoagulation. Patients with pulmonary emboli or lower extremity deep venous thrombosis should be treated according to current guidelines. Patients with PH-LD who also have evidence of chronic thromboembolic disease should be treated lifelong with warfarin to achieve a target international normalized ratio of 2 to 3. In other selected patients with PH-LD who are at low risk for

complications from anticoagulation treatment, warfarin can be considered with the recognition that there are no clear benefits. Anticoagulation with direct thrombin inhibitors and factor Xa antagonists has not been studied in the treatment of PH-LD, and these agents currently have no role in the treatment of PH-LD.

Digoxin

In a small study of patients with COPD and cor pulmonale, digoxin had a favorable effect on RV function without changes in pulmonary function, exercise capacity, or symptoms.¹⁴⁸ Current data do not support a recommendation for the routine use of digoxin in patients with cor pulmonale from PH-LD. Digoxin may be better tolerated than negative inotropic agents, such as β -blockers or calcium channel blockers for rate control in patients with PH-LD who develop arrhythmias such as atrial fibrillation. It must be emphasized that patients with COPD are particularly sensitive to digoxin, and close attention to dosage and electrolyte balance to prevent toxicity is necessary.

Lung Volume Reduction Surgery

The effects of *lung volume reduction surgery* (LVRS) on pulmonary hemodynamics remain controversial. LVRS has been shown to improve symptoms and quality of life in patients with emphysema and may improve pulmonary hemodynamics by improving oxygenation and reducing hyperinflation; by contrast, pulmonary hemodynamics may be worsened by removing or altering the pulmonary vasculature. Results of retrospective studies have shown variable effects of LVRS on hemodynamics; some have shown improvement in RV function¹⁴⁹ and reduction in wedge pressure,¹⁵⁰ whereas others have found an increase in PPA and PVR.^{151,152} The prospective cardiovascular sub-study of the National Emphysema Treatment Trial attempted to clarify the hemodynamic effects of LVRS by randomizing 110 patients to either LVRS or medical therapy.¹⁵³ Six months after treatment, hemodynamics were similar in both groups with the exception of a small reduction in wedge pressure in the LVRS group. Based on these results, LVRS is not currently recommended for routine treatment of PH-LD.

Phlebotomy for Polycythemia

If severe polycythemia is present, phlebotomy may be helpful, although clinicians are frequently reluctant to undertake this type of therapy today. An elevated hematocrit above 40% is known to increase viscosity and PVR (see Fig. 6-6). Phlebotomy in patients with polycythemia and chronic hypoxemia may also improve RV ejection fraction, exercise tolerance, and neuropsychological function.⁶³ For those with an elevated hematocrit, for example above 55%, phlebotomy should be considered and, if the patient benefits, repeated as needed to maintain a lower hematocrit.¹⁵⁴⁻¹⁵⁶

Iron Supplementation

Experiments in animals and human tissue cells have revealed that the hypoxia-inducible factor family of transcription factors are integral to regulation of the pulmonary vascular response to hypoxia.¹⁵⁷ Hypoxia-inducible factor is primarily regulated by oxygen-dependent proteosomal degradation, a process that is up-regulated or

down-regulated based on iron availability. A study in humans showed that intravenous iron infusions into healthy iron-replete volunteers blunted the pulmonary vasoconstrictor response to hypoxia, whereas a reduction in available iron through chelation to those same volunteers enhanced the pulmonary vasoconstrictor response to hypoxia.¹⁵⁸

In a follow-up study, PPA was assessed by echocardiography in 22 healthy volunteers at sea level.¹⁵⁹ Subjects were then taken to 4340 m for 3 days and treated with either intravenous iron or saline; repeat assessment showed a reduction in PASP in iron-treated patients compared to controls. Another trial evaluated the effects of standard therapy, phlebotomy, followed by iron infusion or saline infusion in 11 patients with chronic mountain sickness.¹⁵⁹ Following phlebotomy, all patients developed iron deficiency with an increase in PASP of 9 mm Hg that did not reverse acutely with intravenous iron treatment. Further randomized trials are needed; however, these studies suggest that evaluation for and correction of iron deficiency in patients with cor pulmonale may be beneficial.

PAH-Specific Therapies

Multiple therapies are now available with proven efficacy in the treatment of PAH (see Chapter 58). Acute hemodynamic benefits in PH-LD have been demonstrated with some of these agents^{160,161}; however, none of these therapies have had long-term benefits in patients with PH-LD.^{161a} Adverse effects, including worsening hypoxemia from reversal of physiologic ventilation-perfusion matching and reduction in systemic blood pressure from peripheral vasodilator effects, have also been seen.^{161,162} Additionally, studies of IPF patients treated with *endothelin receptor antagonists* (ERAs) have resulted in worse outcomes in the experimental group compared to placebo.^{163,164}

A comprehensive review of the studies of PAH-specific treatment in patients with PH-LD can be found in the online version of this chapter at *ExpertConsult*.

Current guidelines discourage the use of PAH-specific therapy in PH-LD patients because of lack of efficacy and risk for adverse effects.^{120,122} These agents might be considered in highly selected patients such as those who also have evidence of concomitant group 1 PAH or group 4 chronic thromboembolic PH and to manage right heart failure in PH-LD patients awaiting lung transplant. If treatment with PAH-specific therapies is considered, we recommend consultation at a PH center of excellence before initiating therapy and, if possible, enrollment in a clinical trial.

TREATMENT OF DECOMPENSATED RV FAILURE

Management of patients with decompensated RV failure from cor pulmonale must focus on improvement of the underlying pulmonary disorder.¹²³ The precipitating event for decompensation in patients with stabilized chronic cor pulmonale from either COPD or infiltrative lung disease is often an associated upper respiratory infection. Increased secretions and infection are likely to tip the balance toward further arterial hypoxemia, hypercapnia, and acidemia, which aggravate PH and worsen ventricular contractility, resulting in cardiac decompensation.

Of major concern in patients with PH-LD is that pharmacologic reversal of hypoxic pulmonary vasoconstriction with vasodilators may increase pulmonary blood flow to poorly ventilated or nonventilated alveoli and cause arterial PO_2 to fall despite a drop in PPA. Ventilation-perfusion mismatching also affects carbon dioxide elimination; therefore minute ventilation may increase to compensate for the retention of carbon dioxide, although arterial PO_2 may still fall.¹⁶⁵ Another practical problem limiting the use of pulmonary vasodilators is that very often they also act as systemic vasodilators and cause significant hypotension.

Calcium Channel Blockers. Calcium channel blockers are not useful in the treatment of PH-LD. In a study of 53 patients with COPD and PH, treatment with nifedipine reduced PVR at baseline by 23% at rest and 35% during exercise, but the benefits were no longer seen after an average of 13 months of treatment.¹⁶⁰ Another study randomized 20 patients with COPD and mild PH to either placebo or nifedipine. There were no acute improvements with the first dose of nifedipine, and 18 months later cardiac output was slightly higher in nifedipine-treated patients accompanied by a nonsignificant reduction in arterial PO_2 . In another study of felodipine in 13 patients, hemodynamics were improved and gas exchange remained stable at 12 weeks compared to baseline, but exercise tolerance was not improved.¹⁶⁶ Due to the lack of long-term benefits and potential side effects from calcium channel blockers (worsening hypoxemia, systemic hypotension, and peripheral edema), we recommend against attempts to treat PH-LD with calcium channel blockers.

Endothelin Receptor Antagonists. Three ERAs are approved by the Food and Drug Administration for the treatment of PAH. Bosentan and macitentan are dual ET_A and ET_B receptors, and ambrisentan is a selective ET_A receptor antagonist.¹⁶⁷ Studies of ERAs in lung disease have been designed to evaluate the effects of endothelin blockade on lung fibrosis and have not specifically included patients with PH-LD.

BUILD 3 (Bosentan Use in Interstitial Lung Disease) was a large, randomized trial of bosentan to reduce the rate of IPF worsening or death. Results of BUILD 3 showed no significant difference in the primary end point of rate of IPF worsening or death in the 407 patients treated with bosentan versus the 209 in the placebo group. Another study evaluated the effects of bosentan on exercise capacity in patients with severe or very severe COPD; at the end of 12 weeks, only 16 of 20 patients randomized to bosentan remained in the treatment group with the remainder dropping out because of adverse effects.¹⁶⁸ There was no difference in exercise capacity in the bosentan-treated group compared to the placebo group, and, in addition, there was a significant reduction in arterial oxygenation and quality of life in the bosentan-treated patients.

In Artemis-IPF, the largest study of ET_A receptor antagonists in the treatment of IPF, ambrisentan was studied in patients with IPF with minimal lung fibrosis.¹⁶³ The study was terminated early because interim analysis suggested a low likelihood of meeting the primary end point. Analysis of data from patients who were enrolled showed that those in the ambrisentan group were more likely than control

subjects to experience disease progression (27.4% vs. 17.2% in the placebo group); this end point was primarily driven by higher rates of hospitalization in the ambrisentan group.

The effect of macitentan on forced vital capacity was studied in patients with IPF in the MUSIC trial, in which 178 subjects were randomized to macitentan or placebo. Hemodynamic assessments were not reported in this study. After 12 months there was no difference in change from baseline forced vital capacity, but there was a trend toward a higher rate of worsening of IPF in the macitentan group.¹⁶⁴

In summary, in patients with lung disease no benefits to treatment with ERAs have been demonstrated, and the Artemis-IPF and MUSIC studies show ERAs may be harmful in this population. From these findings we conclude that ERAs should not be used to treat PH-LD, and further studies of ET_A receptor antagonists in patients with lung disease seem unlikely.

Prostacyclin and Its Analogues. Prostanoids such as epoprostenol are potent pulmonary vasodilators normally synthesized by the pulmonary vascular endothelium, and exogenous prostanoids have a central role in the treatment of PAH.¹⁶⁹ Studies in animals and humans have shown that hypoxemia results in relative prostanoid deficiency^{170,171}; however, studies in patients have not found treatment with prostanoids to be beneficial in PH-LD.

Intravenous epoprostenol was studied in a small number of patients with respiratory failure secondary to COPD. Those treated with epoprostenol experienced significant reductions in arterial PO_2 , most likely from nonselective pulmonary and systemic vasodilatation, resulting in a worsening ventilation-perfusion relationship.¹⁷²

Studies of inhalational prostanoids were performed because it was thought they might cause less nonselective pulmonary vasodilation, preserving ventilation-perfusion relationships and minimizing hypoxemia. Beneficial effects using inhaled prostanoids were shown in several early trials. In one small study, treatment with aerosolized iloprost resulted in preferential pulmonary vasodilation and significant reduction in $P\bar{P}A$ and PVR.¹⁷³ Another study evaluated the effects of a single dose of inhaled iloprost in 10 patients with PH-COPD and right ventricular abnormalities; patients had a statistically significant improvement of 49.8 m on the 6MWD without a significant change in arterial PO_2 and without adverse hemodynamic effects.¹⁷⁴

The same beneficial effects of inhaled prostanoids were not seen in a more recent randomized double-blind crossover trial of inhaled iloprost in COPD patients with right heart catheterization-confirmed PH.¹⁷⁵ In this study, placebo, 10 μ g and 20 μ g of iloprost were studied in 16 patients during three separate study visits. There was no difference in 6MWD after either dose of iloprost compared to placebo. A significant reduction in arterial SO_2 was seen at rest, and a nonsignificant reduction was seen with exercise. The subgroup of 3 participants with right ventricular abnormalities and more severe PPA did have an improvement in exercise tolerance. Based on these results, inhaled prostanoids should not be routinely used in these patients due to lack of benefit and risk for worsening hypoxemia; however, it is possible that inhaled prostanoids may be beneficial in some highly selected patients with PH-LD. Further

well-designed trials with appropriately selected study populations are needed to clarify the role of inhaled prostanoids in this population.

Nitric Oxide. NO is produced by the enzyme NO synthase within endothelial cells and activates guanylate cyclase, increasing smooth muscle cell cyclic guanosine monophosphate, which causes pulmonary vasodilation.^{176,177} A possible role in the treatment of PH-LD has been suggested based on data demonstrating that NO reverses hypoxic pulmonary vasoconstriction in healthy volunteers.^{178,179} Similar to inhaled prostanoids, inhaled NO would be expected to cause less nonselective dilation of the pulmonary vasculature and less ventilation-perfusion mismatch. Furthermore, inhaled NO is inactivated before it reaches the systemic circulation so that less systemic hemodynamic effects would be expected. Only limited, conflicting data are available regarding the effects of NO on hypoxemia in advanced COPD; one small study reported a decrease¹⁸⁰ and another no change¹⁸¹ in arterial PO_2 after inhaled NO. However, because treatment with NO is technically challenging, costly, and associated with a variety of potential adverse effects, clinical use remains impractical at this time.

Phosphodiesterase Type 5 Antagonists. Sildenafil and tadalafil are selective inhibitors of cyclic guanosine monophosphate-specific phosphodiesterase type 5 and cause pulmonary arteriolar smooth muscle cell relaxation and vasodilation. Additionally, sildenafil has antifibrotic activity that has been tested in patients with lung disease.

The acute effects of sildenafil on hemodynamics and oxygenation were studied at rest and with exercise in 20 patients with COPD and mild PH after a single dose of 20 mg or 40 mg of sildenafil.¹⁶¹ There was a significant 21% reduction in resting PPA 1 hour after sildenafil that was accompanied by worsening gas exchange with a reduction in arterial PO_2 of 9%. A similar reduction in PPA was seen during exercise with no significant change in oxygenation; concomitant studies showed that worsening hypoxemia was related to worsening of ventilation-perfusion matching after sildenafil.

Three studies have attempted to address the effects of sildenafil on exercise tolerance in patients with COPD. In the first, sildenafil was administered to 15 COPD patients for 3 months; compared to baseline, there was no difference in the right ventricular stroke volume measured by MRI or in exercise tolerance measured by cardiopulmonary exercise testing and the 6MWD.¹⁸² The effects of sildenafil on exercise capacity were studied in 10 patients in a randomized double-blind placebo-controlled crossover study.¹⁸³ Patients with PH were specifically excluded from this study. After 14 days of sildenafil treatment, there was no difference in exercise capacity, but there was worsening of oxygenation and quality of life with increasing symptoms and adverse events in the sildenafil group. Another study randomized 63 patients with COPD and moderate PH documented by echocardiography to treatment with sildenafil for 3 months

during pulmonary rehabilitation; in this study sildenafil had no effect on exercise capacity or oxygenation.¹⁸⁴

The acute effects of sildenafil have also been evaluated in patients with interstitial lung disease. Sixteen hospitalized patients with pulmonary fibrosis were treated with inhaled NO and then randomized to receive open-label intravenous epoprostenol (mean dose 8 ng/kg/min) or a single dose of oral sildenafil 50 mg.¹⁶² All three agents reduced the PVR index to a similar extent. However, only inhaled NO and sildenafil reduced the PVR-to-SVR ratio. Intravenous epoprostenol also decreased mean systemic arterial pressure and PO_2 values, owing to ventilation-perfusion mismatching. By contrast, during treatment with inhaled NO and sildenafil, ventilation-perfusion matching was maintained. Therefore, among patients in this study, sildenafil exerted a selective pulmonary arterial vasodilatory effect without worsening hypoxemia.

The effects of sildenafil on exercise tolerance in patients with PH-IPF were examined in two studies. In one small open-label study 14 patients with IPF and mild PH received sildenafil 20 to 50 mg three times daily for 12 weeks.¹⁸⁵ At the end of the study, of the 11 patients who completed the 6MWD, 9 demonstrated an improvement in the mean 6MWD of 49 m (90% confidence interval, 17.5 to 84 m). The largest study of sildenafil in patients with IPF to date was STEP-IPF (Sildenafil Trial of Exercise Performance in Idiopathic Pulmonary Fibrosis).¹⁸⁶ In this study, patients with IPF were randomized to either sildenafil ($n = 89$) or placebo ($n = 91$) for 12 weeks of treatment without any assessment for the presence or severity of PH. The primary end point of improvement in 6MWD was not met; however, patients taking sildenafil had improved dyspnea, quality of life, and less deterioration in oxygenation.

Overall, the results of these studies are highly variable but suggest that in certain patients with lung disease sildenafil might confer some early hemodynamic and symptomatic improvement, potentially at the expense of worsening ventilation-perfusion matching and worsening oxygenation and without any clear long-term benefits. Further well-designed studies are needed to determine if there is a role for these agents in PH-LD.

Riociguat. Riociguat is a soluble guanylate cyclase agonist approved by the Food and Drug Administration in 2013 for the treatment of PAH that was studied in patients with PH-LD. In an open-label trial, riociguat was studied in 23 patients with interstitial lung disease who also had PH with a PPA above 30 mm Hg and no more than mild airflow obstruction. At 12 weeks there were small but statistically significant improvements in cardiac output, PVR, and SVR compared to baseline. The PVR-to-SVR ratio remained largely unchanged, and the PPA was increased in some patients, suggestive of an increase in blood flow that may be attributable to reduction in the SVR. There was also statistically significant worsening of oxygenation. These findings of no improvement in hemodynamics and worsening oxygenation suggest that riociguat should not be considered in patients with PH-LD.

Improvement in RV performance is best accomplished not only by correcting acidemia, but also by reducing the afterload facing the RV (i.e., reducing \overline{PPA}). Correction of arterial hypoxemia through the administration of an increased concentration of oxygen lowers PPA in patients with hypoxic pulmonary vasoconstriction. Improvement in alveolar ventilation with intubation and mechanical ventilation helps eliminate the acute hypercapnia and acidemia that depress myocardial contractility.

In the setting of severe acute RV decompensation with hypoperfusion, low-dose intravenous infusion of dopamine and dobutamine (1 to 2 mg/kg/min) may improve cardiac output, blood pressure, and renal perfusion. Oxygen and dopamine have been shown to be equipotent renal vasodilators in hypoxic COPD. Low-dose dopamine infusion (2 to 5 mg/kg/min) can increase cardiac output, reduce PVR, and improve oxygen delivery.¹⁸⁷ Higher infusions of dopamine (10 mg/kg/min) have been shown to increase diaphragmatic blood flow and contraction.¹⁸⁸ Although they are effective in acute decompensated RV failure, the value of these agents in chronic cor pulmonale is yet to be determined.

Key Points

- Pulmonary hypertension is present in approximately 25% of patients with advanced lung disease and is associated with significantly worsened symptoms and functional impairment and with increased morbidity and mortality.
- The pathogenesis of pulmonary hypertension due to lung disease involves combinations of hypoxic pulmonary vasoconstriction and pulmonary vascular remodeling, which are related to anatomic restriction and/or obliteration of the pulmonary vascular bed from alveolar destruction, fibrosis, inflammation, thrombosis, and the effects of mitogenic mediators specific to the underlying lung disease.
- The diagnostic evaluation of patients with pulmonary hypertension due to lung disease should include a comprehensive evaluation to identify any other medical conditions that can elevate pulmonary arterial pressure, including sleep-disordered breathing and chronic thromboembolic pulmonary hypertension.
- The optimal approach to management of patients with pulmonary hypertension due to lung disease and

cor pulmonale includes aggressive treatment of the underlying lung disease and administration of supplemental oxygen.

- Currently there are no U.S. Food and Drug Administration–approved therapies for the treatment of pulmonary hypertension due to lung disease, apart from the administration of oxygen; accordingly, early referral for evaluation of lung transplantation is important, and, if specific treatment for pulmonary hypertension is warranted, expert consultation before initiating therapy is recommended.

INTRODUCTION AND DEFINITIONS

Pulmonary vasculitis is a general term that encompasses a wide variety of individual disease entities, all of which share a unifying finding of inflammation and destruction of blood vessels within the lung. More specifically, these entities are characterized pathologically by the presence of a variety of types of cellular infiltration within vessel walls, resulting in vessel destruction, and ultimately tissue necrosis. The clinical features of a specific disorder are determined by the site, size, and type of vessel involved as well as the relative amounts of vessel inflammation, destruction, and tissue necrosis. While simple to define, the recognition, diagnosis, and management of the pulmonary vasculitides are among the most demanding challenges in medicine. Protean in their presentation and variable in their clinical evolution, their signs and symptoms fully overlap with infection, adverse medication reaction, connective tissue disease, and malignancy. Even in patients with a known vasculitis, separating active disease from complicating infection, drug toxicity, or some combination thereof, will challenge the most skilled physician. Amplifying the problem, these diseases are often deadly; even when appropriately treated, the long-term survival among patients with *antineutrophil cytoplasmic antibody positive* (ANCA)-associated vasculitis (AAV) is considerably less than for the general population—88% survival at 1 year and 78% survival at 5 years, or a relative mortality risk of 2.6.¹ Despite these hurdles, the astute clinician can make the diagnosis, initiate and manage therapy, and minimize complications by keeping some broad concepts in mind.

CLASSIFICATION

The major clinical benefit of classifying the vasculitides is to provide a framework that allows for an appreciation of the presenting features of disease. The most current broadly accepted system is the 2012 Revised International Chapel

Hill Consensus Conference nomenclature,² which is based on clinicopathologic presentations rather than etiology or disease mechanism (Table 60-1). It is important to recall that this classification system cannot be used to inform diagnosis or management. *The diagnosis of vasculitis relies upon the bedside clinician recognizing patterns of disease made up of specific clinical, laboratory, imaging, and pathologic features.* There are no strict classification criteria or clinical diagnostic guidelines. It is up to the clinician to determine whether or not the preponderance of the data supports the diagnosis of a pulmonary vasculitis.

Nevertheless, there are still useful paradigms by which to organize one's diagnostic approach. A commonly used scheme uses vessel size (large, medium, and small). The large vessels are made up of the aorta, its largest branches (e.g., carotid, cerebral, iliac, subclavian, and femoral vessels) and the main pulmonary artery. The medium-sized vessels are made up of the main visceral arteries (e.g., renal, hepatic, coronary, and mesenteric vessels), whereas the small vessels are made up of arterioles, capillaries, and venules. There can be overlap, because the small and large vessel vasculitides sometimes involve medium-sized arteries, but large and medium vessel vasculitides generally do not involve vessels smaller than arteries.

A second classification scheme uses ANCA. The identification of these antibodies in the 1980s revolutionized thinking regarding diagnosis and pathogenesis (see later). The vasculitides that are most commonly encountered in the practice of pulmonary medicine, the primary, idiopathic small-vessel vasculitides, are also ANCA-positive and described as AAV. These include *granulomatosis with polyangiitis* (GPA) (formerly known as Wegener granulomatosis), *eosinophilic granulomatosis with polyangiitis* (EGPA) (formerly known as Churg-Strauss syndrome), and *microscopic polyangiitis* (MPA). A third approach to classification is sometimes used, defining the vasculitides by the presence or absence of granulomatous inflammation. Two of the AAVs—GPA and EGPA—as well as the large vessel vasculitides, Takayasu arteritis and *giant cell arteritis* (GCA), are characterized by the presence of granulomatous inflammation.

Figure 60-1 Normal appearance of pulmonary artery, small muscular pulmonary artery, and vein. **A**, Pentachrome (Movat) stain illustrating the relationship between pulmonary artery (*) and bronchiole (#). **B**, Muscular pulmonary artery in the peripheral lung showing internal and external elastic lamina in black (pentachrome/Movat stain). **C**, Small pulmonary vein in peripheral lung showing one elastic lamina in black (pentachrome/Movat stain).

Table 60-1 Classification of Vasculitis^{1,143,144}

PRIMARY IDIOPATHIC

Small Vessel

Granulomatosis with polyangiitis (Wegener granulomatosis)
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss vasculitis)
Microscopic polyangiitis
Idiopathic pauci-immune glomerulonephritis
Idiopathic capillaritis

Medium Vessel

Polyarteritis nodosa
Kawasaki disease

Large Vessel

Takayasu arteritis
Giant cell arteritis

PRIMARY IMMUNE COMPLEX MEDIATED

Anti-glomerular basement membrane disease (Goodpasture syndrome)
IgA vasculitis (Henoch-Schönlein purpura)
Cryoglobulinemic vasculitis
Hypocomplementemic urticarial vasculitis

SECONDARY VASCULITIS

Classic autoimmune disease
 Systemic lupus erythematosus
 Rheumatoid arthritis
 Antiphospholipid antibody syndrome
Infection
Paraneoplastic
Drug-induced (e.g., propylthiouracil)
Inflammatory bowel disease

European populations. Among the individual disorders, the annual incidence of GPA ranges from 4.9 to 10.5 per million, of EGPA from 0.5 to 4.2 per million, and of MPA from 2.7 to 11.6 per million. The prevalence of GPA ranges from 24 to 157 per million, of EGPA from 7 to 38 per million, and of MPA from 0 to 66 per million. Among the secondary vasculitides, the best data are for rheumatoid arthritis-associated vasculitis (incidence of 12.5 per million), although with the advent of biologic therapy, this rate appears to have decreased dramatically. Finally, the incidence of *systemic lupus erythematosus* (SLE)-associated vasculitis is 3.6 per million.³

NORMAL VASCULAR ANATOMY AND HISTOLOGY

In a group of diseases pathologically defined by abnormalities of the vasculature, understanding the normal organization and location of the arterial and venous blood supplies in the lung is useful in appreciating their clinical features. The lung has a dual blood supply: the pulmonary and the bronchial circulations. The bronchial arteries arise from the systemic circulation (aorta and intercostal arteries) and form a plexus in the bronchial wall. The bronchial veins associate closely with the bronchial arteries, although neither is commonly affected in the pulmonary vasculitides (see Chapter 1).

During embryogenesis, the pulmonary arterial system forms in tandem with the branching bronchial buds and is recognized on histologic examination by its close proximity to the corresponding bronchi or bronchiole (Fig. 60-1A; see also Fig. 1-17). In the normal lung, arteries and adjacent airways are similar in size to bronchi and bronchioles, so marked differences can be an indication of pathology.⁴ The arterial system consists of four components: elastic arteries, muscular arteries, arterioles, and capillaries. *Elastic arteries* are larger than 0.5 to 1 mm in diameter and can be recognized macroscopically. They are composed of an endothelial cell lining layer, a smooth muscle medial layer, and have well-developed, multiple elastic laminae. *Muscular arteries* are between 100 and 500 μ m in diameter, and are composed of an endothelial cell lining, a smooth muscle media bound by two elastic laminae (inner and outer), and a collagenous adventitia. The smooth muscle layer progressively

EPIDEMIOLOGY

The true overall incidence and prevalence of vasculitis is difficult to gauge, in that all of the available epidemiologic studies contain significant flaws that limit their applicability. The available data are neither geographically nor ethnically diverse, and the case definitions and acquisition methodology vary from study to study. With these caveats in mind, GCA is the most frequently recognized systemic vasculitis with an annual incidence of 150 to 350 per million persons older than age 50 years. Persons of Nordic heritage appear at particularly high risk, especially in older age. The primary systemic vasculitides have an overall prevalence estimated at between 90 and 300 per million in

decreases in thickness until one reaches the arterioles. *Arterioles* are defined by a diameter of less than 100 μm and the absence of a muscular media; however, these can become muscularized in a variety of diseased states. The arterioles connect with capillaries. *Capillaries* are characterized by the presence of a single layer of endothelial cells and an underlying basement membrane. They form part of the alveolar septa, and are the most common vessel affected in pulmonary vasculitis. On hematoxylin and eosin stains of surgical lung biopsies, identifying the capillaries is difficult because a number of cells—endothelial cells, fibroblasts, and mononuclear inflammatory cells—all are normal occupants of the alveolar septa.

The location of the pulmonary veins in the mature lung is typically away from the bronchi and within interlobular septa, because the embryonic pulmonary veins form branches that grow into the mesenchyme surrounding the lung buds. Although pulmonary veins can be distinguished from pulmonary arteries by their single elastic lamina (see Fig. 60-1B and C), in the diseased lung, there can be reduplication of the elastic lamina, causing “arterialization” of the pulmonary veins, and anatomic location may be the only indicator of vessel type.

HISTOPATHOLOGY OF VASCULITIS

Although the diagnosis of vasculitis never relies on histopathology alone, both the diagnosis and subclassification can be suggested based on the size and location of the affected vessels (Fig. 60-2). The findings common to all the pulmonary vasculitides are inflammatory cell infiltration (inflammation) of the vessel wall with destruction of elastic laminae (in the case of arteries and veins) and often, an accompanying fibrinoid necrosis. The lining endothelial cells may show abnormalities, with subendothelial inflammation (endothelialitis), cellular disruption and even loss of endothelial cells. The type of inflammation can vary widely; neutrophilic, eosinophilic, lymphoplasmacytic, or mixed infiltrates can all be seen. Granulomatous inflammation, consisting of poorly formed granulomas or multinucleated giant cells and/or epithelioid histiocytes, is of particular

importance because one level of classification is based on its presence or absence (see earlier).

The term *capillaritis* is used to describe vasculitis of capillaries; however, it is often difficult to identify the capillary on routine hematoxylin and eosin stains, much less the endothelial disruption necessary to make the diagnosis. Therefore identifying neutrophils and nuclear debris (evidence of apoptosis) within alveolar septal walls is used as an indirect sign of capillaritis.

Not only do the size and type of vessel affected provide important information, but changes to the associated lung parenchyma provide additional clues. For example, a nodular parenchymal infiltrate is commonly seen in GPA, with microabscesses, necrosis, eosinophilic pneumonia, organizing pneumonia and/or hemorrhage. The specific pathologic findings associated with each entity are discussed in more detail later.

PATHOGENESIS AND ETIOLOGY

Most of the vasculitic syndromes are hypothesized to be mediated by immunopathogenic mechanisms that arise in response to antigenic stimuli. Why some patients develop vasculitis in response to a particular stimulus, while others do not, is unknown. The etiology is likely multifactorial, including genetic predisposition, environmental exposures, and individual immune responses. A recent large genome-wide association study found both major-histocompatibility complex and non-major histocompatibility complex associations with AAV, confirming a genetic contribution to disease development.⁵ Three broadly defined mechanisms have been proposed: pathogenic autoantibody formation with neutrophil activation and endothelial damage, immune complex deposition, and pathogenic lymphocyte responses. For each of these mechanisms, some combination of the direct immunologic attack and endothelial and vascular wall response appears responsible for the subsequent clinical and pathologic findings.⁶

A large variety of autoantibodies have been described, including the antiglomerular basement membrane (collagen type IV) antibodies seen in anti-glomerular basement membrane disease, antiendothelial cell antibodies, anti-laminin antibodies, antiphospholipid (e.g., anti-beta-2

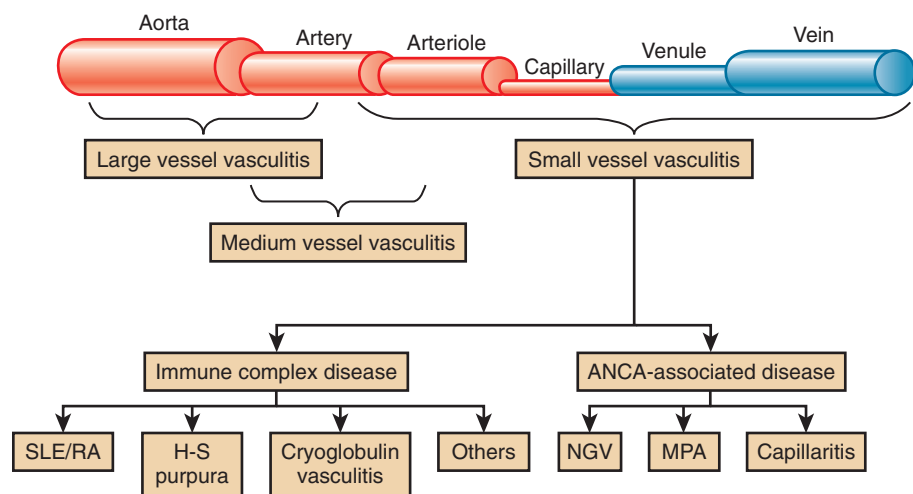

Figure 60-2 Relationship between vessel size and mechanism. The small vessel vasculitides are diagrammed as immune complex disease and ANCA-associated disease. ANCA, antineutrophil cytoplasmic antibodies; H-S, Henoch-Schönlein; MPA, microscopic polyangiitis; NGV, necrotizing granulomatous vasculitis; SLE/RA, systemic lupus erythematosus/rheumatoid arthritis.

glycoprotein I and anticardiolipin) antibodies, and ANCA, among others. Of these, the best studied mechanism is that proposed for the AAVs, especially GPA. While the clinical syndrome was described in the 1930s,^{7,8,9} it was not until 1982 that specific autoantibodies, now known as ANCA, were described.¹⁰ While the role of ANCA in the pathogenesis of disease remains to be fully elucidated, there is compelling in vitro, animal model and clinical evidence supporting a key role for the pathogenicity of ANCA. Some clinical data suggest that, while not sufficient to cause disease alone, the presence of ANCA appears to be required for the development or recurrence of systemic disease. These data include (1) the link between the presence of these autoantibodies, the development of systemic vasculitic complications, and prognosis; (2) the effectiveness of the anti-CD20 monoclonal antibody rituximab at reducing ANCA titers and controlling disease activity; and (3) the finding that patients who become ANCA negative are at low risk for clinical relapse.

Mechanistically, the majority of the clinically significant ANCAs are directed against microbicidal components used by neutrophils in host defense. These antibodies have been shown to have significant proinflammatory effects with activation of neutrophils, monocytes, and endothelial cells.¹¹ ANCA stimulate the release of chemokines from neutrophils, monocytes, and endothelial cells, enhance the expression of cell adhesion molecules on endothelium, and activate primed neutrophils to release proteolytic enzymes and oxygen radicals.^{12,13} Each of these steps can contribute to the vascular and tissue damage seen. Moreover, an animal model has demonstrated the ability of *antimyeloperoxidase antibodies* (anti-MPO) to induce necrotizing vasculitis, further strengthening the link between antibody formation and disease development.^{14,15}

The trigger for ANCA production and persistence is poorly understood. A role for active infection/inflammation in the disease pathophysiology has been proposed because there is evidence that chronic or concurrent infections can lead to disease exacerbation or relapse.¹⁶⁻¹⁸ ANCA positivity has also been directed against a variety of antigens seen with viral, fungal, bacterial, and protozoal infection, as well as subacute bacterial endocarditis and cystic fibrosis.^{19,20} It has been hypothesized that infections may give rise to ANCA through molecular mimicry and contribute to their persistence through T- and B-cell stimulation by microbial superantigens. For example, some patients with AAV have been shown to elaborate antibodies against *lysosome-associated membrane protein 2* (LAMP2) found in neutrophils. The LAMP2 protein bears close homology to the bacterial adhesin FimH protein expressed in gram-negative bacteria, and antibodies against LAMP2 and FimH are capable of producing glomerulonephritis in animal models.²¹

Other potential mechanisms for the development of vasculitis include the direct invasion of the vessel wall by pathogenic organisms (e.g., bacterial, mycobacterial, spirochetal, rickettsial, fungal, viral), leading to an acute, direct vasculitic response as well as deposition of circulating immune complexes in the blood vessel wall. This deposition of immune complexes can lead to complement activation, anaphylatoxin production, and mast cell degranulation. Mast cell degranulation leads to release of vasoactive substances and the anaphylatoxins can act as chemotactic

agents for neutrophils, eosinophils, and mononuclear inflammatory cells. The prototypical disease for this mechanism is SLE, in which complexes of nuclear antigens such as DNA, immunoglobulins, and complement proteins lead to vascular injury.^{22,23} Other immune complex-mediated vasculitides include rheumatoid vasculitis, Henoch-Schönlein purpura, and cryoglobulinemic vasculitis.

Aberrant lymphocyte responses are hypothesized to contribute to both the granulomatous inflammation seen in GPA and EGPA (T cells) as well as the production of ANCA (B cells). Activated T cells may be found in the peripheral blood of patients with GPA, even when the disease is in remission, and markers of T-cell activation appear to correlate with disease activity.²⁴ Furthermore, there appears to be an increase in Th17-positive T-cell populations (believed to promote autoimmunity) and reduced regulatory T-cell (Treg) functionality, suggesting a loss of tolerance.²⁴⁻²⁷ Finally, there is increased elaboration of Th1 cytokines in patients with GPA (tumor necrosis factor- α , *interleukin* (IL)-1 and IL-8), while there is increased interferon- γ , IL-4, IL-5, and IL-13 in patients with EGPA.^{28,29}

INITIAL DIAGNOSIS

CLINICAL SCENARIOS SUGGESTIVE OF VASCULITIS

The importance of the initial history in the evaluation of a patient with suspected vasculitis cannot be overemphasized. Symptoms that initially seem unrelated and of only minor importance may need to be explored more fully because both vasculitis and its mimics (e.g., connective tissue diseases, infection, malignancy, drug toxicity) present with and evolve through a variety of confusing clinical manifestations. Similarly, a careful physical examination may reveal otherwise asymptomatic disease that suggests the presence of a systemic disorder. To put some order to this, the identification of particular clinical scenarios can suggest the presence of a systemic vasculitis.³⁰

Destructive Upper Airway Lesions

Chronic refractory sinusitis in which primary infectious, allergic, and anatomic causes have been excluded and/or when destructive soft tissue or bone lesions or chronic ulcerative lesions are present can raise suspicion of an underlying vasculitis.

Chest Imaging Findings of Cavitory or Nodular Disease

Whereas a wide variety of nonspecific findings may be seen on chest imaging, the presence of nodular or cavitory disease should raise one's suspicion. While infection and malignancy are the most common explanations, in the correct clinical setting a vasculitis, particularly an AAV, should be considered. Illustrating this point, cavities are found in 35% to 50% and nodules in 55% to 70% of patients with GPA.^{31,32}

Diffuse Alveolar Hemorrhage (see Chapter 67)

Diffuse alveolar hemorrhage (DAH) refers to the presence of diffuse intra-alveolar bleeding generally from the alveolar

Figure 60-3 Capillaritis showing disruption of the alveolar septa by infiltrates of neutrophils and nuclear debris. The septal borders are vague, indicating wall damage.

capillaries and less frequently from the precapillary arterioles and postcapillary venules. While patients “classically” present with hemoptysis, diffuse alveolar opacities, and a drop in hematocrit, DAH must be considered in all patients with unexplained air space disease. Hemoptysis can be difficult to identify because it is often only intermittent and is not seen at all in up to one third of patients. The alveolar opacities do not have to be diffuse, and a drop in hematocrit can be difficult to document. Therefore DAH should be considered in patients with otherwise unexplained diffuse alveolar opacities, particularly when these findings complicate symptoms of a connective tissue disease or new onset renal insufficiency. While an increase in the diffusion capacity of more than 30% over baseline can be suggestive, it is rare to obtain a diffusing capacity in an acutely ill patient.

DAH is diagnosed by bronchoalveolar lavage. With the bronchoscope in wedge position, serial aliquots (30 to 60 mL in volume) of sterile saline are instilled and aspirated (for a total volume of 100 to 300 mL). If the serial aliquots of fluid reveal an increasingly hemorrhagic or, at a minimum, a persistently bloody return, then the diagnosis of DAH is made (see Fig. 67-3). The finding of DAH is not diagnostic of vasculitis. DAH can be caused by diseases associated with the histopathologic finding of capillaritis (including the primary idiopathic and secondary vasculitides) (Fig. 60-3), as well as by diseases with diffuse alveolar damage and bland hemorrhage (Table 60-2). When DAH is a complication of an AAV, capillaritis is almost always found; however, bland hemorrhage may be the only finding, particularly if treatment has been initiated. When DAH with pathologic pulmonary capillaritis is the only clinical manifestation of a vasculitis, the term *idiopathic pauci-immune pulmonary capillaritis* is used, and this syndrome is classified in the family of primary idiopathic small-vessel vasculitides regardless of ANCA status.

Acute Glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is defined by the identification of an active urinary sediment on urinalysis, including hematuria (especially with dysmorphic red cells), red cell casts, and proteinuria (>500 mg/d) in the setting of a rising blood urea nitrogen and serum creatinine. The microscopic examination of the urine needs to be

Table 60-2 Causes of Diffuse Alveolar Hemorrhage^{145,146}

WITH HISTOPATHOLOGIC CAPILLARITIS

Classic vasculitides

- Primary idiopathic small vessel vasculitis
- ANCA-associated—GPA, EGPA, MPA
- Isolated pauci-immune pulmonary capillaritis

Immune complex mediated

- Anti-glomerular basement membrane disease (Goodpasture syndrome)
- IgA vasculitis (Henoch-Schönlein purpura)
- Cryoglobulinemic vasculitis

Secondary vasculitis

- Classic autoimmune disease
- Systemic lupus erythematosus
- Other (e.g., rheumatoid arthritis, scleroderma)
- Primary anti-phospholipid antibody syndrome

Hematopoietic stem cell transplantation

- Drug-associated disease (chemotherapeutic agents, diphenylhydantoin)

Behçet disease

WITHOUT CAPILLARITIS (BLAND HEMORRHAGE)

Idiopathic pulmonary hemosiderosis

- Coagulopathy
- Mitral stenosis
- Inhalation injury
- Drug-associated disease (chemotherapeutic agents, penicillamine, trimellitic anhydride, amiodarone, nitrofurantoin)

ANCA, antineutrophil cytoplasmic antibody; EGPA, eosinophilic granulomatosis with polyangiitis; GPA, granulomatosis with polyangiitis; MPA, microscopic polyangiitis.

performed on a fresh urine sample because red cell casts and dysmorphic red cells degenerate within 30 to 60 minutes in a freshly voided sample. Once RPGN is identified, the differential diagnosis includes AAV, idiopathic pauci-immune glomerulonephritis (isolated small-vessel renal vasculitis), SLE, Goodpasture syndrome, post-infectious glomerulonephritis, IgA nephropathy, Henoch-Schönlein purpura, essential cryoglobulinemia, and membranoproliferative glomerulonephritis.³³⁻³⁶

Pulmonary-Renal Syndrome

Pulmonary-renal syndromes are classically defined as the presence of both DAH and RPGN. However, whenever a destructive airway lesion or chest imaging finding of nodules or cavities is seen together with renal insufficiency, vasculitis should also be considered. When this happens, the primary differential includes the AAVs, Goodpasture syndrome, and SLE.

Palpable Purpura

The presence of palpable purpura on physical examination implies a small vessel, cutaneous vasculitis.³⁷ The most common explanation is a cutaneous (hypersensitivity) vasculitis secondary to a drug reaction; however, the AAV, cryoglobulinemia, connective tissue diseases, infections, and malignancy should all be considered.

Mononeuritis Multiplex

Defined by the development of abnormalities in two or more peripheral nerve distributions, mononeuritis multiplex should raise particular suspicion.^{38,39} A variety of other central or peripheral nervous system symptoms can also be seen, including pain, numbness, paresthesias, weakness, or

loss of function (e.g., sudden onset of a foot drop or wrist drop).

Multisystem Disease

Unusual combinations of signs and symptoms that involve multiple organ systems either simultaneously or over time could raise the possibility of a vasculitis. This requires a high index of suspicion from the clinician because items such as constitutional symptoms (e.g., fever of unknown origin), unusual “rashes,” migratory polyarthritides, or “chronic sinus disease” may be relevant when the primary clinical presentation is breathlessness, renal failure, or abnormal findings on chest imaging.

SPECIFIC TESTING

Antineutrophil Cytoplasmic Antibodies

ANCA were first described by Davies and coworkers¹⁰ in the early 1980s in patients with glomerulonephritis and GPA, and were recognized by a pattern of diffuse immunofluorescent staining of ethanol-fixed neutrophils. At nearly the same time, a pattern of perinuclear immunofluorescent staining of ethanol-fixed neutrophils was described in patients with MPA and pauci-immune glomerulonephritis.¹⁰ Currently, three specific *indirect immunofluorescent* (IIF) staining patterns are described: *cytoplasmic* (c-ANCA) (Fig. 60-4A), *perinuclear* (p-ANCA) (see Fig. 60-4B), and *atypical* (a-ANCA). c-ANCA are primarily, but not exclusively, directed against *proteinase 3* (PR3, in azurophilic granules), while the p-ANCA are most commonly directed against myeloperoxidase (MPO, also in azurophilic granules), but with a much wider group of potential intracellular targets. Specific *enzyme-linked immunosorbent assay* (ELISA) testing for PR3 and MPO are commercially available and of considerable clinical utility. These antibodies are closely associated with the small-vessel vasculitides of the lung, GPA, EGPA, and MPA. These “ANCA-associated small-vessel vasculitides” all involve the small vessels and share a number of clinical features including, when present, pauci-immune, crescentic and focal necrotizing glomerulonephritis. However, while ANCA positivity is common in these disorders, it is by no means universal.

Figure 60-4 Indirect immunofluorescent staining patterns of c-ANCA (A) and p-ANCA (B).

The diagnostic utility of ANCA testing is dependent upon the sensitivity, specificity, and positive predictive value of c-ANCA (or anti-PR3) for GPA and p-ANCA (or anti-MPO) for MPA and EGPA. When applied indiscriminately, the positive predictive value of the testing declines dramatically. Mandl and associates⁴⁰ demonstrated that by using clinical guidelines to identify at-risk patients, the positive predictive value of the tests increased without reducing sensitivity. While ANCA testing alone or PR3 and MPO ELISA testing alone are used by many centers as their initial screening test, the combination of ANCA IIF testing plus ELISA testing maximizes their sensitivity.⁴⁰⁻⁴⁴

With the caveats noted earlier, c-ANCA is highly sensitive (90% to 95%) in active, systemic GPA but less so (65% to 85% sensitive) in single organ-limited disease, and even less so for GPA in remission.⁴⁵ Specificity is approximately 90%. In the proper clinical setting, with a very high pretest probability of disease, a positive c-ANCA/anti-PR3 has sufficient positive predictive value to obviate the necessity of a biopsy.⁴⁶ On the other hand, p-ANCA and anti-MPO generally lack sufficient sensitivity and may provide no more than suggestive evidence of EGPA, MPA, or pauci-immune RPGN, because it can also be found in rheumatoid arthritis, Goodpasture syndrome, autoimmune hepatitis, inflammatory bowel disease, and a wide variety of other clinical circumstances.⁴³

Considerable attention has been focused on the utility of ANCA to assess disease activity, particularly the role of rising ANCA titers in predicting relapse.⁴⁸ Unfortunately there appears to be no clear relationship between antibody titers and disease activity. In a prospective interventional study in which PR3-ANCA levels were routinely obtained, decreasing ANCA titers did not predict time to remission and increasing titers did not predict relapse. Increasing titers were associated with a relapse in only 40% of patients over a 12-month period. Therefore the decision to modify therapy in patients with ANCA-associated vasculitis must be a clinical decision based on clinical evidence of disease activity independent of ANCA titers.⁴⁵

Based on high-quality evidence, recommendations have been offered that ANCA testing by IIF should be performed in the appropriate clinical context to detect the labeling pattern and that all positive samples be tested for anti-PR3 and MPO specificity.⁴⁹ A positive test for c-ANCA targeted to PR3 or p-ANCA targeted to MPO has a high sensitivity and specificity for the diagnosis of AAV. It should also be recognized that the absence of a positive test does not rule out a diagnosis of vasculitis. Indeed, while the concept of “ANCA-associated” applies to the patient population as a whole and has implications for pathogenesis, it must be emphasized that an individual patient may well be ANCA (or PR3/MPO) negative and still have what we describe as an AAV. ANCA testing should be performed in accredited laboratories that participate in external quality control programs and undergo regular review of laboratory management and staff performing the assays.⁵⁰

OTHER LABORATORY STUDIES

Cultures of blood and other potentially affected organs (when tissue is obtained) should be performed to exclude infection. Routine laboratories (complete blood count with differential, chemistries, liver function tests, blood urea

nitrogen, and creatinine) should be obtained, although the findings are generally nonspecific. An elevated erythrocyte sedimentation rate and elevated C-reactive protein lack specificity but are common findings. Urinalysis with microscopy should be performed on a fresh sample in all patients, because proteinuria and microscopic hematuria are common early findings in GPA and MPA. Anti-GBM antibodies should be obtained in all patients with pulmonary hemorrhage or a pulmonary-renal syndrome. Antinuclear antibodies and rheumatoid factor can be positive, although high titers; especially with the presence of disease-specific antibodies (e.g., dsDNA, SS-A/SS-B, anti-RNP, anti-Scl-70, anti-centromere antibodies, anti-JO-1) favor a connective tissue disease. IgE and circulating eosinophil counts should be obtained when EGPA is being considered.

CHEST IMAGING

Chest radiography and *computed tomography* (CT) findings are often abnormal even in the absence of symptoms, because more than 80% of patients with GPA and EGPA have some radiographic abnormalities. Specific findings are best described in GPA and include nodular opacities (eFig. 60-1) and masses, particularly those that cavitate (eFig. 60-2), diffuse ground-glass opacification (eFig. 60-3) (especially when DAH is a possibility), consolidation (eFigs. 60-4 and 60-5), atelectasis, and airway complications such as stenoses (eFig. 60-6) and ulcerations (eFig. 60-7). Lymphadenopathy (eFig. 60-8) is not common and is more suggestive of infection or malignancy.⁵¹ Patients with EGPA commonly demonstrate patchy, heterogeneous ground-glass opacities or consolidation as well as evidence of airways disease.

OTHER IMAGING STUDIES

CT of the sinuses (see eFig. 60-7) similarly demonstrates abnormalities in a majority (70% to 90%) of patients with GPA and EGPA, and may help identify destructive or ulcerating disease in patients with GPA. Electrocardiograms and echocardiography are useful in identifying cardiac involvement. The heart is involved in only 5% to 15% of patients with GPA but in as many as 30% to 50% of patients with EGPA and potentially carries a high attributable mortality. Routine screening of patients with proven or suspected AAV with electrocardiogram and echocardiography is commonly performed. Additional imaging or functional studies are determined by the clinical scenario and the signs and symptoms present in the individual patient (e.g., abdominal CT, brain CT/MRI, nerve conduction studies).

BRONCHOSCOPY

Bronchoscopy is primarily used to look for malignancy, infection, stenotic or ulcerative upper airway or endobronchial lesions, pulmonary eosinophilia, and alveolar hemorrhage. Bronchoalveolar lavage should be grossly examined for evidence of alveolar hemorrhage, sent for culture (bacterial, fungal, and mycobacterial), cytology, and a differential cell count. Transbronchial biopsies may provide important information that helps exclude infection or malignancy; however, they are rarely useful in making a

positive diagnosis of vasculitis. When Hoffman and colleagues⁵² performed 59 transbronchial biopsies in 48 patients with GPA, only four provided useful diagnostic features. Schnabel and coworkers⁵³ found that transbronchial biopsies provided support for a diagnosis of GPA in only 2 of 17 patients, while otolaryngologic examination and biopsy of the clinically involved areas of the upper respiratory tract yielded useful information in 13 of 19 patients with GPA.

DIAGNOSTIC BIOPSY

While a confident diagnosis may occasionally be made without tissue, diagnostic tissue biopsy remains necessary for a definitive diagnosis. Biopsy of the skin or upper airway is generally safe and these sites are easily accessible, but they less commonly yield diagnostic tissue when compared with a needle biopsy of the kidney or a surgical biopsy of the lung. When Hoffman and colleagues⁵² examined 82 open lung biopsies in patients with small-vessel vasculitis, diagnostic features were found in 90%. Renal biopsy is often performed to determine the cause of an acute glomerulonephritis. Specific features indicative of vasculitis such as granulomatous inflammation or vascular necrosis are rarely found; however, the presence of focal, segmental necrotizing glomerulonephritis without immune deposits (pauci-immune)^{52,54-56} is strongly suggestive of a systemic vasculitis.

It is important to appreciate that the pathologic features of vasculitis often overlap with other inflammatory lesions such as necrotizing *infectious* granulomas. In addition, not all the histopathologic features of vasculitis may be present because of the timing of the biopsy and/or modification of the histology secondary to prior treatment, particularly corticosteroids. Because of this, it is critical for the surgeon, pulmonologist, and pathologist to have a coordinated plan before the biopsy. The clinical differential will dictate the appropriate specimens to collect, including fresh tissue for culture and immunofluorescence (the presence of characteristic immunofluorescence patterns, such as IgA deposition in Henoch-Schönlein purpura, linear IgG deposition in Goodpasture syndrome, and irregular immunoglobulin and complement deposition in SLE can be diagnostic) as well as for formalin-fixation.

SPECIFIC CLINICAL DISORDERS

As systemic disorders, essentially all of the vasculitides can involve the lung. This involvement ranges from diffuse alveolar hemorrhage to cavitary nodules, parenchymal inflammation, pleural disease, vascular aneurysms, and thrombotic and thromboembolic phenomena. A full accounting of each described disorder and its pulmonary manifestations is beyond the scope of this chapter. However, the primary idiopathic small-vessel vasculitides deserve special attention.

GRANULOMATOSIS WITH POLYANGIITIS

GPA is the most common of the ANCA-associated small-vessel vasculitides, arises at any age (generally 40 to 60

years), and equally affects the sexes. It is clinically recognized by its ability to involve the upper airway (e.g., chronic sinusitis and/or otitis, upper airway ulceration and/or structural deformity, subglottic or endobronchial stenosis), lower respiratory tract (e.g., chest symptoms of cough, chest pain, shortness of breath, hemoptysis and/or chest imaging abnormalities), and kidney (e.g., glomerulonephritis) (Table 60-3). However, involvement of all three sites is neither necessary nor common at presentation. For example, even though 80% to 90% of patients ultimately develop renal disease, as few as 40% have renal involvement at time of first presentation.⁵⁷⁻⁵⁹ Constitutional symptoms as well as skin, eye, musculoskeletal, peripheral, and central nervous system disease are common.^{36,57-59} Chest imaging findings are abnormal in most patients, showing alveolar, mixed, or interstitial opacities (eFigs. 60-3 through 60-5), and nodular (see eFig. 60-1) or cavitory disease (see eFig. 60-2).^{31,32} A positive c-ANCA is seen in 90% to 95% of active systemic disease but in only 60% to 65% in limited disease.^{47,60-62} The histopathology on surgical lung biopsy is

dependent on the stage of the disease and whether there has been prior immunomodulatory treatment. Involvement of a small and medium-sized vessel with necrotizing vasculitis with granulomatous inflammation and parenchymal necrosis, often with a geographic appearance, is characteristic (Fig. 60-5A).⁶³⁻⁶⁷ The pathologic manifestations can be divided into major and minor histologic features. The three major features include (1) lung parenchymal necrosis, either in the form of geographic necrosis or neutrophilic microabscesses; (2) vasculitis (generally involving small to medium-sized arteries, but which can also involve veins and capillaries) (see Fig. 60-5B and C); and (3) granulomatous inflammation (see Fig. 60-5D).

Although the inflammation in GPA is typically described as granulomatous, it is often mixed and includes granulomas, giant cells, neutrophils, lymphocytes, plasma cells, histiocytes, and eosinophils. The minor histologic criteria include organizing pneumonia (70% of cases), diffuse alveolar hemorrhage (10% of cases), eosinophilia, and bronchocentric granulomatosis (1% of cases).^{63,68} If the biopsy

Table 60-3 Clinical Findings in the ANCA-Associated Vasculitides

	GPA	EGPA	MPA
Constitutional	Common. Includes fatigue, malaise, fevers, and weight loss.	Common. Weight loss, fatigue, fevers, myalgias and arthralgias.	Very common. Generally precedes renal disease by months.
Pulmonary	70% to 95% of patients with respiratory symptoms or chest imaging abnormalities. Tracheobronchial and endobronchial disease in 10% to 50%.	Asthma essentially universal. Patchy, heterogeneous radiographic opacities in >70%.	10% to 30% with diffuse alveolar hemorrhage.
Renal	50% to 90% of patients.	20% to 50% of patients.	RPGN is almost universal.
Upper airway	70% to 95% of patients. Destructive or ulcerating lesions are suggestive.	Sinusitis, polyposis, and/or rhinitis in ≥ 70% of patients. Generally not destructive.	5% to 30% with sinus disease most common.
Musculoskeletal	Arthralgias, synovitis and myalgias in up to 80%.	Arthralgias and myalgias reported in up to 50%.	Arthralgias and myalgias in at least 50% of patients.
Eyes	25% to 60% of patients. Vision-threatening disease including uveitis, ocular ulcers.	<5%	Up to 30% of patients. May be clinically silent.
Cardiac	5% to 25% of patients. Conduction delays or other electrocardiographic abnormality, systolic or diastolic dysfunction, pericarditis, or coronary artery vasculitis.	30% to 50% of patients and a major cause of mortality. Conduction delays, or other electrocardiographic abnormality, systolic or diastolic dysfunction, pericarditis, or coronary artery vasculitis.	10% to 20%. Congestive heart failure and pericarditis have been described.
Gastrointestinal	<10%	30% to 50% of patients and a major cause of morbidity and mortality. Hemorrhage, abdominal pain, infarct, or perforated viscus.	35% to 55% of patients. Findings similar to polyarteritis nodosa. Pain, bleeding, and ischemia. Rare visceral aneurysms.
Dermatologic	Up to 60%. Palpable purpura, ulcers, nodules or vesicles.	50% to 70% purpura, nodules, papules, leukocytoclastic vasculitis with or without eosinophils.	35% to 60% of patients with purpura common.
Neurologic	Both central and peripheral nervous system involvement.	Mononeuritis multiplex in 50% to 75%. Central nervous system in 5% to 40%.	Mononeuritis multiplex in 10% to 50%.
Chest imaging	Abnormal in >80%. Alveolar, interstitial, or mixed opacities, often with nodular and/or cavitory disease.	Opacities in >70%. Airways disease common (airway wall thickening, hyperinflation).	Opacities in 10% to 30%. Pleural effusions in 5% to 20%.
ANCA	ANCA positive > 90% and c-ANCA/anti-PR3 ELISA positive in > 85% with generalized active disease.	ANCA positive in 30% to 70% with most of these being p-ANCA/anti-MPO positive.	ANCA positive in 50% to 75% with most of these being p-ANCA/anti-MPO positive.

ANCA, antineutrophil cytoplasmic antibody; anti-MPO, antimyeloperoxidase antibodies; anti-PR3, antiproteinase antibodies; EGPA, eosinophilic granulomatosis with polyangiitis; ELISA, enzyme-linked immunosorbent assay; GPA, granulomatosis with polyangiitis; MPA, microscopic polyangiitis; RPGN, rapidly progressive glomerulonephritis.

is performed early in the course of disease, some of the classic histologic findings may be absent. With prior treatment, there may be no significant inflammatory infiltrates and the only (nonspecific) clue may be scarring of arteries and/or airways.⁶⁹ A distinctive, but uncommon, histologic appearance is isolated capillaritis (see Fig. 60-3).

Appropriately treated disease is associated with a 5-year survival rate of 75%. While it is commonly assumed that active vasculitis itself accounts for this excess mortality, the mortality can be attributed to a variety of causes, including infection, malignancy, thromboembolic disease, cardiac disease, renal failure, and drug toxicity. Indeed, the leading cause of death among patients with AAV is infection rather than uncontrolled disease activity.⁷⁰ Poor outcomes correlate with advanced age, lack of upper airway involvement, more severe renal impairment, pulmonary involvement (particularly with alveolar hemorrhage), cardiac involvement, and high-level anti-PR3 positivity.⁷¹

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS (see Chapter 68)

EGPA is a specific ANCA-associated small-vessel vasculitis that is clinically distinct from GPA and MPA (see Table 60-3), affects adults of all ages, and affects both genders equally. Its presentation often overlaps with the eosinophilic lung diseases (chronic eosinophilic pneumonia, allergic bronchopulmonary mycosis, drug reactions, hypereosinophilic syndrome, parasitic infection, asthma/atopic disease) and difficult-to-control asthma/atopy. The syndrome has its own triad of (1) asthma, (2) hypereosinophilia, and (3) necrotizing vasculitis that classically has a three-phase presentation with the initial presence of atopy/rhinitis/sinusitis/asthma, followed by an eosinophilia, and finally vasculitis. However, the three phases do not need to present sequentially, and the asthma may even postdate the vasculitis. Asthma is essentially universal and, while EGPA may present with any degree of severity and duration, severe (steroid-requiring) asthma is common with patients having asthma for 7 to 10 years before the vasculitis diagnosis.⁷¹ The upper airway is commonly involved with chronic rhinitis and sinusitis (with or without nasal polyposis), although generally without any of the destructive features associated with GPA.

Chest imaging is abnormal in more than two thirds of patients.⁷² Most commonly, waxing and waning parenchymal opacities (ground-glass attenuation and consolidation) (eFig. 60-9) and less commonly nodules are seen on CT of

the chest. Effusions can be seen in 10%. In contrast to GPA and MPA, pulmonary hemorrhage and glomerulonephritis are much less common in EGPA.⁷²⁻⁷⁶ Significant cardiac (conduction abnormalities, systolic or diastolic dysfunction, intracavitary thrombus, pericarditis) or gastrointestinal disease (perforation, ischemia, bleeding) are dreaded and well recognized complications. ANCA is positive in a perinuclear IIF pattern (p-ANCA) in 30% to 70% of cases, with peripheral eosinophilia (absolute eosinophil count > 1500 cells/ μ L) almost universal at some point in the course.

Recently, it has been identified that patients with EGPA segregate into two distinct clinical phenotypes. One subset is characterized by a greater incidence of neurologic, renal, gastrointestinal, and cutaneous involvement that is more commonly ANCA or MPO-positive (i.e., shares a high degree of overlapping features with GPA and MPA). The other subset of patients shares features with the hypereosinophilic syndromes, namely cardiac manifestations, migratory lung opacities (eosinophilic pneumonia), and an ANCA-negative/MPO-negative serologic profile.⁷⁶⁻⁷⁸

Pathologically, patients with EGPA demonstrate both a necrotizing, small-vessel vasculitis and an eosinophil-rich cellular infiltrate.^{79,80} The diagnostic findings on lung biopsy include eosinophilic pneumonia, necrotizing vasculitis, and granulomatous inflammation (Fig. 60-6). The vasculitis consists of artery, vein, or capillary wall infiltration by lymphocytes and eosinophils. The granulomas often show central areas of necrosis with abundant necrotic eosinophils, surrounded by palisaded histiocytes and multinucleated giant cells. Findings highly suggestive of EGPA include eosinophilic pneumonia and necrotizing vasculitis; findings suggestive of EGPA include eosinophilic pneumonia and parenchymal necrosis.⁸⁰

Mortality is generally due to cardiac complications (which constitute up to half of EGPA-related deaths), gastrointestinal complications, or status asthmaticus and respiratory failure.^{72,73,81} While mortality rates of up to 40% were described in the 1970s, more recent data suggest that, when adequately treated, patients may have a normal life span.⁸² A recent single center study demonstrated that a comprehensive vasculitis center-based management strategy of patients with EGPA without heart failure had a survival rate no different than that of a matched general population.⁸³ Overall 5-year survival rates have been estimated at 68% to 100%.⁷¹

In the late 1990s, an association between the use of leukotriene inhibitors and EGPA had been suggested in a number of case reports and case series^{84,85}; this led to the

Figure 60-6 Eosinophilic granulomatosis with polyangiitis. **A**, Outline (*dashed line*) of a destroyed vessel. Note the marked eosinophilic infiltration. **B**, A small vein showing destruction of its wall by eosinophils. There is an accompanying eosinophilic pneumonia characterized by numerous clusters of eosinophils within the air spaces. Hemorrhage is also present.

concern that leukotriene inhibitors may help promote the biologic conversion of severe asthma/atopic disease to EGPA.⁸⁶ However, analyses of postmarketing surveillance data and a number of patient cohorts over the mid-2000s argued against this relationship, leading to the hypothesis that these excess cases were due either to reporting bias or to the unmasking of EGPA precipitated by the withdrawal of corticosteroids.^{82,87-89} However, in 2010, an analysis of the U.S. Food and Drug Administration Adverse Event Reporting Database found that only 36% of cases of leukotriene-associated EGPA had preexisting clinical evidence suggesting possible EGPA or had an associated tapering of the patient's corticosteroids; hence the majority of cases of EGPA associated with leukotriene antagonists could not otherwise be explained.⁹⁰ Similar findings were identified in the U.K. Committee on Safety of Medicines' "yellow card" scheme. As such, the pendulum has swung back toward favoring a very small but potentially real relationship between the use of leukotriene antagonists and the development of EGPA.

MICROSCOPIC POLYANGIITIS

Clinically, MPA is an ANCA-associated small-vessel vasculitis generally heralded by weeks to months or longer of profound constitutional symptoms (fever, asthenia, fatigue, malaise, myalgias, arthralgias) followed by the development of renal disease, generally RPGN (see [Table 60-3](#)). It is more common in males, with an average age of onset in the sixth decade. Its clinical manifestations overlap with those of polyarteritis nodosa, which accounts for the decades of confusion over their relationship. The glomerulonephritis is essentially universal, whereas the lungs are involved in a minority of patients (10% to 30%).⁹¹⁻⁹³ For patients in whom lung disease develops, diffuse alveolar hemorrhage/capillaritis is the most common manifestation ([eFig. 60-10](#)). Pulmonary fibrosis is uncommon but associated with a high mortality rate.⁷¹ The skin is involved in more than half of patients, most commonly with purpura. The peripheral

nervous system (most commonly with mononeuritis multiplex) is involved more frequently than the central nervous system, and the gastrointestinal tract becomes involved, with bleeding and ischemia, with some frequency.⁹⁴ ANCA is positive in a perinuclear pattern in 50% to 75% of cases.

Pathologically, a focal, segmental necrotizing vasculitis and a mixed inflammatory infiltrate without granulomata are seen. The vasculitis of MPA affects venules, capillaries, and arterioles. Neutrophilic capillaritis (see [Fig. 60-3](#)) is the classic histologic finding in the lung, with pulmonary alveolar hemorrhage and hemosiderin-laden macrophages ([Fig. 60-7A and B](#)). As the lesions heal, plugs of organizing pneumonia may fill air spaces, resulting in an organizing pneumonia-like pattern. Unlike the other small-vessel vasculitides, MPA lacks granulomatous inflammation. The overall 5-year survival rate has been estimated to range from 45% to 75%.⁷¹ Relapses after successful induction therapy are common (25% to 33%),⁹¹ but are usually less severe and responsive to therapy.

TREATMENT

GENERAL PRINCIPLES

Because therapy for the vasculitides involves aggressive immunosuppression with cytotoxic agents and corticosteroids, treatment-related complications are common and can be severe. Given the risks directly associated with therapy, the intensity of immunosuppression must be titrated to the severity of the disease; therefore the intensity of therapy is not driven by the diagnosis, but rather by disease severity. The goal is achieving disease control while minimizing the risk of treatment-related adverse events. As such, instruments and systems to accurately grade disease severity have been developed as documented in [Table 60-4](#) and accompanying references. Additionally, similar to cancer therapy, treatment is divided into two phases, an initial "remission-induction" phase to control

Figure 60-7 Microscopic polyangiitis. **A**, Low power view of diffuse alveolar hemorrhage. The air spaces are filled with red blood cells and the alveolar septa show concomitant inflammatory thickening. **B**, Alveolar hemorrhage demonstrating the smudged, homogeneous appearance of the disrupted red blood cells in the air spaces. Occasional hemosiderin-laden macrophages can be seen in the center. **C**, Hemosiderin-laden macrophages within the air spaces indicating chronic alveolar hemorrhage.

Table 60-4 European Vasculitis Study Group Disease Severity and First-Line Treatment Options for Induction Therapy				
Disease Classification	Constitutional Symptoms	Renal Function	Threatened Organ Function	Treatment Options for Induction
Limited	No	Serum creatinine < 120 mmol/L (1.4 mg/dL)	No	Corticosteroids OR methotrexate OR azathioprine
Early generalized	Yes	Serum creatinine < 120 mmol/L (1.4 mg/dL)	No	Cyclophosphamide + corticosteroids OR Methotrexate + corticosteroids
Active generalized	Yes	Serum creatinine < 500 mmol/L (5.7 mg/dL)	Yes	Cyclophosphamide + Corticosteroids OR Rituximab + corticosteroids
Severe	Yes	Serum creatinine > 500 mmol/L (5.7 mg/dL)	Yes	Corticosteroids + plasma exchange + cyclophosphamide (or rituximab)
Refractory	Yes	Any	Yes	Consider investigational or compassionate use agents (see text)
Maintenance of remission	No	N/A	No	If patient was induced with cyclophosphamide, then: azathioprine ± low-dose oral corticosteroids OR Methotrexate ± low-dose oral corticosteroids If patient was induced with rituximab, then: fixed schedule rituximab ± low-dose oral corticosteroids

active disease and a “maintenance” phase to maintain disease remission while lowering treatment-related risk. Regardless of the phase of therapy, both disease-specific and drug-specific monitoring is required, focused on the early identification of disease activity and adverse events (e.g., infection and drug toxicity). Clinicians should be familiar with the common toxicities associated with each drug and

have a standard protocol for the monitoring of potential treatment-related adverse effects during both remission-induction and maintenance therapy. Not to be forgotten, oxygen therapy when needed, the treatment of comorbid disease, appropriate vaccinations, *Pneumocystis jirovecii* prophylaxis, physical and occupational therapy, a regular exercise regimen to maintain conditioning, proper

nutrition along with achieving and maintaining ideal body weight, proper sleep hygiene, bone health, and psychosocial support should be provided to help minimize the morbidity associated with these diseases.

As noted earlier, treatment recommendations depend on an accurate assessment of disease severity. The *European Vasculitis Study Group* (EUVAS) has devised a clinically useful grading system that categorizes active disease into one of five levels of severity: (1) limited, (2) early, generalized, (3) active, generalized, (4) severe, and (5) refractory, or as (6) in remission. Clinical criteria and first line treatment recommendations appear in Table 60-4. Alternatively, the French Vasculitis Study Group has validated an alternative, the *five-factor score* (FFS). Originally validated in EGPA and MPA, the FFS has now been validated across all AAV.⁹⁵ The FFS is calculated by adding +1 point for the presence of each of the following: (1) renal insufficiency, (2) clinically significant gastrointestinal disease, (3) cardiac symptoms, (4) the *absence* of upper airway (ear, nose, or throat) involvement, and (5) age 65 and older. Five-year mortality rates for scores of 0, 1, and 2 or more are 9%, 21%, and 40%, respectively.⁹⁵

To improve interobserver reliability and to make disease activity and vasculitic damage scoring more objective, reliable, and reproducible, specific instruments have been developed. The Birmingham Vasculitis Activity Score (version 3.0) is an inventory of signs, symptoms, and laboratory findings commonly associated with AAV that is commonly used in clinical trials to grade and quantify vasculitic disease activity.⁹⁶ The instrument quantifies the history, examination, review of systems, and routine laboratories obtained by the bedside clinician caring for the vasculitis patient. The Vasculitis Damage Index similarly quantifies vasculitic damage.⁹⁷ Both of these instruments are well validated and commonly used in the conduct of clinical trials.

REMISSION-INDUCTION

Limited Disease

Limited disease refers to localized disease of the upper airway. There are no systemic symptoms, end organ function is not threatened, and there is no renal involvement. While there are few data to inform management decisions in this subgroup, expert opinion holds that therapy can often be limited to a single agent, such as corticosteroids, azathioprine, or methotrexate. While some authors have recommended *trimethoprim/sulfamethoxazole* (T/S) alone for this group,⁹⁸ it is not clear whether T/S alone represents effective therapy and therefore remains controversial (see later). For more aggressive limited disease, therapy outlined for early generalized or active generalized disease may be necessary.

Early Generalized Disease

Early generalized disease differs from active generalized disease by the absence of an immediate threat to specific organ function. Still, patients with early generalized disease have constitutional symptoms and measurable end-organ involvement. While treatment recommendations have traditionally been similar for both early generalized and active

generalized disease (cyclophosphamide plus corticosteroids), investigators have sought alternative approaches for the early, generalized disease, hypothesizing that a less aggressive treatment regimen may be sufficient to induce disease remission while decreasing the potential for drug toxicity. To this end, the EUVAS-sponsored Methotrexate versus Cyclophosphamide for 'Early Systemic Disease' trial (NORAM) was performed. In this head-to-head comparison of methotrexate versus cyclophosphamide, the investigators found that oral methotrexate was as efficacious as oral cyclophosphamide in the induction of disease remission in early generalized disease at 6 months (84% vs. 83%), albeit with a longer time to remission (5.2 months vs. 3.2 months).⁹⁹⁻¹⁰¹ Moreover, while methotrexate had fewer side effects, its rate of relapse was also higher (74% vs. 42%). Indeed, the long-term follow-up data from this trial demonstrated that the cyclophosphamide arm was superior to methotrexate as measured by cumulative relapse-free survival, and no differences in major adverse events were observed between treatment groups.¹⁰² Thus, while both agents may be "acceptable" first-line therapy in early disease, cyclophosphamide appears to provide more effective overall disease control.

Mycophenolate mofetil and azathioprine have also been proposed as possible alternatives to cyclophosphamide in the induction of disease remission in patients with early, generalized disease; however, data are sparse. Silva and colleagues¹⁰³ published a small case series evaluating mycophenolate mofetil combined with corticosteroids for induction of remission in patients with MPA and mild-moderate renal disease with promising preliminary results (70% sustained remission at 18 months). The EUVAS study group is in the process of conducting a large prospective, randomized, controlled phase II/III trial comparing the efficacy of mycophenolate with cyclophosphamide for the induction of disease remission. Trial results are expected.

Active Generalized Disease

Fauci's early studies⁵⁸ of cyclophosphamide plus corticosteroids dramatically changed the field of vasculitis therapy, and this therapeutic combination has remained primary first-line therapy for the treatment of active generalized disease. The combination of oral cyclophosphamide plus oral corticosteroids in this initial study yielded a remission rate of greater than 90%. Before the advent of this regimen, the prognosis for patients with AAV was uniformly poor with 5-year mortality rates as high as 85%.

To reduce the side effects and toxicity associated with oral cyclophosphamide induction therapy, while preserving high rates of disease remission, a number of clinical trials have been performed looking at alternative regimens. Pulsed intravenous cyclophosphamide was compared head-to-head with oral cyclophosphamide in the EUVAS-sponsored CYCLOPS trial (Daily Oral versus Pulse Cyclophosphamide for Renal Vasculitis).¹⁰⁴⁻¹⁰⁶ While the investigators found that intravenous cyclophosphamide was as effective as oral cyclophosphamide at inducing disease remission and was associated with fewer side effects, long-term follow-up data found that the risk of relapse was significantly higher (29.5% vs. 20.8%).^{106,107} On the other hand, no significant differences were found between the two groups regarding survival, renal function, or adverse events.

Both ANCA and B cells have been implicated in the pathogenesis of AAV and, as such, the anti-CD20 monoclonal antibody rituximab was proposed as a potential therapy. After a number of promising case series, two large randomized, multicentered controlled clinical trials were performed comparing rituximab with cyclophosphamide for the induction of disease remission.^{108,109} The RAVE trial (Rituximab vs. Cyclophosphamide for ANCA-Associated Vasculitis) compared rituximab with daily oral cyclophosphamide. In this study, rituximab was shown to be noninferior to cyclophosphamide as measured by the primary end point of disease remission plus successful tapering of corticosteroids at 6 months.¹¹⁰ Subgroup analysis found that there was no difference in efficacy for the treatment of alveolar hemorrhage and that rituximab may be superior for the treatment of relapsing disease. No differences were noted in the rate of adverse events. Similar findings were found in the RITUX-VAS trial (Rituximab vs. Cyclophosphamide in ANCA-Associated Renal Vasculitis) in which rates of sustained remission, median time to remission, and adverse events were similar between the two treatment groups.¹¹¹ As such, rituximab now also represents first-line therapy for the induction of disease remission in GPA and MPA with active generalized disease.

Severe Disease

Severe disease is defined by an immediate threat of organ failure or death. Thus patients with severe renal disease (creatinine > 5.7 mg/dL), DAH, cardiomyopathy/heart failure, or other organ-threatening disease would be classified as having severe disease. Based on the results of the MEPEX trial (Randomized Trial of Plasma Exchange or High Dosage Methylprednisolone as Adjunctive therapy for Severe Renal Vasculitis) in a cohort of patients with severe renal disease, the addition of plasma exchange therapy to the standard cyclophosphamide plus corticosteroid regimen is recognized to be superior to high-dose, pulsed intravenous steroids as measured by dialysis-free survival (69% vs. 49%).¹¹²⁻¹¹⁸ Based on a 20-patient case series and a number of case reports, this strategy also appears to be effective for the treatment of DAH.¹¹⁷ Additional therapies described at the case report level for patients with unresponsive DAH include activated human factor VII to control ongoing refractory hemorrhage in patients with respiratory failure^{119,120} and extracorporeal membrane oxygenation, which has been used to treat refractory hypoxemic respiratory failure in patients with severe hemorrhage until other interventions have had a chance to work.¹²¹

Refractory Disease

Patients who have not responded to high-dose corticosteroids, cytotoxic agents, and plasma exchange are deemed to have refractory disease. There is no standard therapy that has been shown to work in this group of patients, and one must consider the use of novel or experimental agents. Fortunately, advances in the treatment of vasculitis have steadily reduced the numbers of patients with refractory disease. Treatments such as intravenous immunoglobulin, deoxyspergualin (an antitumor and immunosuppressant agent), and antithymocyte globulin¹²² have all been suggested. When feasible, patients with refractory disease

should be cared for in centers with specialized expertise in the management of vasculitis.

Maintenance

Maintenance therapy is designed to preserve disease control while reducing the risk or severity of medication-related adverse effects. During this phase of treatment, patients who undergo induction of remission with cyclophosphamide are generally converted to therapy with azathioprine or methotrexate, often combined with low-dose corticosteroids. Patients who undergo induction of remission with rituximab are generally treated with repeated dosing of rituximab plus low-dose corticosteroids. However, the optimal maintenance regimen for patients who are induced with rituximab remains an active area of investigation. As with all cytotoxic agents, these agents must be introduced with drug-specific monitoring to identify adverse effects as early as possible. Additional agents that have been used in selected patients include mycophenolate mofetil, leflunomide, and cyclosporine.^{99,100,123-126}

The timing of transition from the induction agent to the maintenance therapy had been a subject of debate, with one school of thought arguing that patients should have defined courses of therapy to “consolidate” the induction of remission, whereas another school of thought argued that clinical evidence of disease activity or lack thereof should serve as the chief determinant of the time to transition to maintenance therapy. The results of the CYCAZAREM trial (Cyclophosphamide vs. Azathioprine for Remission in Generalized Vasculitis) demonstrated that patients with active generalized vasculitis may be transitioned from oral cyclophosphamide to azathioprine once a clinical remission (using defined criteria) has been reached (generally within 3 to 6 months). Patients in the clinically determined (early) transition group demonstrated no increase in the rate of relapse, disease activity scores, or change in renal function.¹²⁷

As with induction therapy, a number of clinical trials have been conducted looking for pharmacologic agents that might offer superior results with regard to maintenance of remission and/or adverse effects relative to azathioprine. Weekly methotrexate has been compared head-to-head with daily oral azathioprine in a large, randomized, controlled trial and has been found to be equally efficacious for maintenance of disease remission; however, the methotrexate arm was found to have a significantly higher rate of adverse events (19% vs. 11%).¹²⁸ Similarly, mycophenolate mofetil was compared head-to-head with azathioprine in the IMPROVE trial (International Mycophenolate Mofetil Protocol to Reduce Outbreaks of Vasculitides). In this trial, azathioprine was found to be superior to mycophenolate for maintenance of disease remission with no differences in the adverse event rate.¹²⁹ The German Vasculitis Study Group has reported good outcomes in patients maintained on leflunomide in small clinical trials, comparable to those reported with azathioprine, but these results have yet to be more widely replicated.^{130,131} Thus azathioprine remains first-line therapy for maintenance of disease remission, with methotrexate as the most attractive alternative for patients who cannot tolerate azathioprine.

For patients who undergo induction therapy with rituximab, management decisions about maintenance therapy are less well informed by data. The early time points studied

in the RAVE and RITUXVAS trials make it difficult to extrapolate the results of those trials to longitudinal management. Options for maintenance therapy following rituximab induction have included corticosteroids alone, corticosteroids plus a cytotoxic agent (similar to therapy in patients induced with cyclophosphamide), or rituximab redosed at regular intervals. Recent data from the University of Cambridge argues for fixed interval rituximab retreatment because this strategy resulted in a markedly reduced relapse rate (26% at 2 years opposed to 86% in those patients followed with prospective management) as well as reduced corticosteroid requirements.¹³² This is a rapidly evolving area, and the reevaluation of the most current literature before making patient management decisions is recommended.

The optimal duration of maintenance therapy is also a source of uncertainty. Absent convincing data and based upon inferences drawn from a number of large clinical trials evaluating differing treatment regimens, experts have advocated for the use of at least 2 years of maintenance therapy before treatment cessation is considered.¹³³ The EUVAS-sponsored REMAIN (Randomised Trial of Prolonged Remission-Maintenance Therapy in Systemic Vasculitis) is designed to answer at least a portion of this question and will compare 24 months of maintenance therapy with 48 months of therapy. Enrollment was completed in 2010 and results are expected in 2015.

Another point of controversy has been the optimal dosage and duration of the corticosteroid component of the treatment regimen. While there is general agreement that “high-dose” corticosteroids should be introduced in patients with active disease as part of their induction therapy (e.g., 1 mg/kg/day of oral prednisone or equivalent) and that this should be “slowly tapered” (e.g., 3 months) toward a “low” maintenance dose (e.g., 5 to 10 mg/day of oral prednisone or equivalent), there is no validated, widely accepted corticosteroid protocol. Whether the corticosteroids should be tapered off or remain at a low dose for a prolonged period of time remains controversial, with experts weighing in on both sides of the argument. With that said, a meta-analysis of thirteen large clinical trials has suggested that patients maintained on some dose (i.e., “non-zero”) of corticosteroids have a lower rate of disease relapse than patients who are weaned entirely off (14% vs. 43%). Still, this has not been replicated in a well-designed, prospective clinical trial and even low-dose corticosteroids carry a risk of adverse side effects.

Finally, the use of T/S^{18,134} may have an adjunctive role in the management of AAV.^{17,135} Studies have demonstrated a reduced frequency of disease relapse in patients who are maintained on T/S compared to those without,¹³⁴ with additional work suggesting that this is related to *Staphylococcus aureus* nasal carriage.^{17,135} Regardless, T/S should be considered for *Pneumocystis jirovecii* prophylaxis in patients maintained on cyclophosphamide or other aggressive immunosuppression regimens, barring a sulfa allergy or other contraindication.

MONITORING FOR COMPLICATIONS

Monitoring for complications is mandatory to minimize the morbidity and mortality of both the disease and its

Table 60-5 Causes of Common Complications of Vasculitides and Potential Interventions

Common Complications	Potential Interventions
Infection	Pneumocystis prophylaxis Vaccination Tailor treatment intensity to disease severity
Drug toxicity	Drug-specific standardized monitoring
Disease recurrence or relapse	Disease-specific monitoring
Comorbid disease	As appropriate for specific disease
Osteoporosis	Bone mineral testing and prophylaxis as appropriate for corticosteroid dose
Venous thromboembolism	Appropriate therapy
Deconditioning	Physical therapy, occupational therapy, routine aerobic exercise, nutrition
Psychosocial distress	Patient support groups

treatment. When clinical deterioration is noted, infection, drug toxicity, disease relapse, thromboembolic disease, and disease processes unrelated to the underlying vasculitis¹³⁶ should all be considered (Table 60-5).

Infection is the leading cause of morbidity and mortality in patients with vasculitis. Infections may present with atypical clinical features or atypical organisms and are frequently difficult to separate from disease activity. Infection may also contribute to triggering or increasing disease activity, and the immune dysfunction associated with disease activity appears to place patients at increased risk for infection, so that disease flares and infections may coincide. Ultimately, infection accounts for 13% to 48% of deaths in patients with vasculitis.^{2,137,138} Combining high-dose glucocorticoids with cytotoxic therapy puts patients at especially high risk.

Historically, up to 50% of patients with an ANCA-associated vasculitis have suffered at least one relapse despite active treatment. Relapses are more common among patients with GPA (40% to 65%) and less common among patients with EGPA (15% to 25%).^{67,139} The features of clinical deterioration during a relapse may be similar to those of the patient's original presentation or there may be novel symptoms and signs that appear in previously unaffected organs. A relapse generally requires reinduction therapy. While disease relapse remains a clinical diagnosis, a recent study applying a proteomic approach to identifying remission in GPA suggests that serum markers may one day permit accurate discrimination between quiescent and active disease.¹⁴⁰

Drug toxicity is also common. In patients with GPA treated with cyclophosphamide, cystitis is described in up to 12%, myelodysplastic syndrome in 8%, and solid malignancy in 5%.¹⁴¹ Ultimately, the bedside clinician must be familiar with the adverse effects associated with the therapies deployed and have a system in place for the monitoring of cytotoxic/immunosuppressive therapies so as to identify toxicity as early as possible. Evidence-based clinical practice guidelines have been developed by the American College of Chest Physicians to assist with informing monitoring practices.¹⁴²

Thromboembolic disease is an underrecognized complication of vasculitis, particularly in the setting of GPA. Patients with GPA have the same rate of venous thromboembolic disease as patients with a known prior history of thromboembolic disease, 7 events per 100 person-years. As such, pulmonary embolism and deep venous thrombosis must also be considered in the differential diagnosis of a patient with new chest or lower extremity symptoms. The rate of thromboembolic disease in MPA and EGPA has yet to be defined.

Key Points

- Pulmonary vasculitis describes a variety of disorders characterized by their ability to cause vascular inflammation, destruction, and tissue necrosis in the lung.
- The presentation, clinical features, and evaluation overlap fully with more common diseases including infection and drug toxicity. The initial history is critical to the evaluation of a patient with suspected vasculitis.
- A confident diagnosis may occasionally be made without tissue biopsy; however, diagnostic tissue biopsy remains necessary for a definitive diagnosis.
- The ANCA-associated vasculitides—granulomatosis with polyangiitis, eosinophilic granulomatosis with polyangiitis, and microscopic polyangiitis—are the most commonly encountered vasculitides in the practice of pulmonary medicine.
- A number of high-quality randomized, controlled trials have enhanced the development of evidence-based treatment recommendations with the expectation of a favorable response.

- Therapy for the vasculitides involves aggressive immunosuppression; consequently treatment-related complications are common and can be severe. Common complications that arise during the course of disease include infection, disease relapse, comorbid disease, and venous thromboembolism.

eFIGURE IMAGE GALLERY

Figure 60-1 Imaging of granulomatosis with polyangiitis: nodules. **A**, Frontal chest radiograph in a patient with granulomatosis with polyangiitis shows numerous bilateral, variably sized pulmonary nodules. **B–E**, Axial chest CT displayed in lung windows confirms the presence of numerous nodules without cavitation. (Courtesy Michael Gotway, MD.)

Figure 60-2 Imaging of granulomatosis with polyangiitis: cavities. **A**, Frontal chest radiograph in a patient with granulomatosis with polyangiitis shows bilateral, variably sized pulmonary cavities. **B–E**, Axial chest CT displayed in lung windows confirms the presence of numerous (arrows) cavities with variable wall thickness; some contain internal opacity, but without air-fluid levels. (Courtesy Michael Gotway, MD.)

Figure 60-3 Imaging of granulomatosis with polyangiitis: diffuse pulmonary opacities due to pulmonary hemorrhage. **A**, Frontal chest radiograph in a patient with granulomatosis with polyangiitis shows multifocal, bilateral, ground-glass opacity and consolidation. **B–E**, Axial chest CT displayed in lung windows shows multifocal ground-glass opacity associated with linear and reticular opacities; prominent peribronchial localization of these opacities is visible in the upper lobes (panel), with numerous air bronchograms as well. These findings are consistent with pulmonary hemorrhage, but are non-specific. (Courtesy Michael Gotway, MD.)

Figure 60-4 Imaging of granulomatosis with polyangiitis: consolidation. **A**, Frontal chest radiograph in a patient with granulomatosis with polyangiitis shows several nodular and masslike areas (*arrowheads*) as well as foci of consolidation (*arrows*). **B–E**, Axial chest CT displayed in lung windows shows nodules and masses (*arrowheads*), with areas of increased opacity and air bronchograms (*arrows*) consistent with consolidation. Some of the masses show internal ground-glass opacity surrounded by consolidation (*double arrowheads*), representing the “reverse ground-glass halo” (or “atoll”) sign, representing areas of pulmonary infarction in this clinical context. (Courtesy Michael Gotway, MD.)

eFigure 60-5 Imaging of granulomatosis with polyangiitis: consolidation. A–D, Axial chest CT displayed in lung windows in a patient with granulomatosis with polyangiitis shows multifocal consolidation (*arrows*), somewhat resembling an organizing pneumonia. Note presence of air bronchograms in some of the opacities (*arrowheads*). (Courtesy Michael Gotway, MD.)

eFigure 60-6 Imaging of granulomatosis with polyangiitis: tracheobronchial stenoses. A and B, Axial chest CT displayed in soft tissue windows in a patient with granulomatosis with polyangiitis shows nodular, circumferential thickening of the trachea and bilateral mainstem bronchi (*arrowheads*). (Courtesy Michael Gotway, MD.)

eFigure 60-7 Imaging of granulomatosis with polyangiitis: upper respiratory tract ulceration. Axial (A) and coronal (B) sinus CT in a patient with granulomatosis with polyangiitis shows opacification of the maxillary sinuses bilaterally (*) and the sphenoid sinus (○). The nasal septum is completely eroded and essentially absent (the nasal septum should normally be located approximately between the two arrowheads). C, Axial contrast-enhanced axial T1-weighted MRI with fat saturation shows extensive inflammatory tissues in the nasopharynx (arrow) as well as absence of the nasal septum (the nasal septum should normally be located approximately between the two arrowheads). (Courtesy Michael Gotway, MD.)

eFigure 60-8 Imaging of granulomatosis with polyangiitis: lymphadenopathy. A–D, Enhanced chest CT shows bilateral peribronchial (arrowheads) and mediastinal (arrows) lymph node enlargement in a patient with granulomatosis with polyangiitis. Lung nodules are also visible (same patient as in eFig. 60-1). (Courtesy Michael Gotway, MD.)

Figure 60-9 Imaging of eosinophilic granulomatosis with polyangiitis. **A**, Frontal chest radiograph shows multifocal hazy increased attenuation associated with a background of linear and reticular opacities, primarily affecting the right lung. **B–E**, Axial chest CT displayed in lung windows shows multifocal ground-glass opacity associated with linear and reticular opacities; these findings are consistent with pulmonary hemorrhage, but are ultimately nonspecific. (Courtesy Michael Gotway, MD.)

Figure 60-10 Imaging of microscopic polyangiitis. **A**, Frontal chest radiograph shows multifocal, bilateral hazy increased attenuation associated with a background of linear and reticular opacities, the latter best seen in the left lung. **B–E**, Axial chest CT displayed in lung windows shows multifocal ground-glass opacity, faintly forming poorly defined centrilobular nodules (*arrow*) in some locations, associated with linear and reticular opacities; these findings are consistent with pulmonary hemorrhage, but are ultimately nonspecific. (Courtesy Michael Gotway, MD.)

Etiology and Pathogenesis
Diagnosis and Treatment

INTRODUCTION

Pulmonary vascular abnormalities are seen in a variety of acquired and congenital conditions. These structural defects include vascular communications that either are confined to the pulmonary circulation, as is the case with pulmonary arteriovenous malformations, or join the systemic to the pulmonary circulations, as with pulmonary sequestration. Aneurysmal dilations of the pulmonary artery and its branches are also considered in this chapter. Although all these conditions are rare, their diagnosis and treatment are important, because many are associated with complications that cause severe morbidity or mortality.

PULMONARY ARTERIOVENOUS MALFORMATIONS

Pulmonary arteriovenous malformations (PAVMs) are abnormal vascular structures that provide a direct capillary-free communication between the pulmonary arterial and pulmonary venous circulations, and hence a *right-to-left* (R-L) shunt. PAVMs are estimated by chest *computed tomography* (CT) scanning to affect 38 per 100,000 individuals (95% *confidence interval* [CI] = 18-76).¹ They range in size and complexity (Fig. 61-1, Fig. 61-2), and also include abnormal communications within the microvasculature (telangiectases). The true anatomic shunts of PAVMs are usually distinguished from the diffusion-perfusion defects that arise in patients with intrapulmonary vascular dilations secondary to the hepatopulmonary syndrome, which is fully described in Chapter 93.

Pulmonary arterial blood passing through these R-L shunts bypasses the alveoli and thus cannot be oxygenated, often leading to hypoxemia. In addition, the absence of a filtering capillary bed allows particulate matter to reach the systemic circulation, where it lodges in other capillary beds, including the cerebral circulation, resulting in embolic cerebrovascular accidents and brain abscesses. It is crucial for the pulmonologist to assimilate the recent data demon-

strating that—regardless of PAVM size—all patients with PAVMs evident on chest CT scan are at risk for paradoxical emboli. Importantly, recent data also confirm that most patients with clinically significant PAVMs do not have respiratory symptoms or profound hypoxemia. The incidence of major, usually neurologic, complications approaches 50% (Table 61-1), with nearly 13% incidence of cerebral abscess and 27% of embolic stroke or transient ischemic attack recorded in all series. These complications can be limited, if the underlying condition is recognized and treated, with embolization, the treatment of choice for almost all patients. Risk-benefit analyses are almost always in favor of treatment, although contraindications should be considered.

ETIOLOGY

PAVMs are most commonly attributed to the inherited vascular disorder *hereditary hemorrhagic telangiectasia* (HHT, or Osler-Weber-Rendu syndrome).³ This vascular condition is usually caused by mutations in the *ENG* gene coding for endoglin (HHT type 1), the *ACVRL1* gene coding for ALK-1 (HHT type 2), or the *SMAD4* gene (juvenile polyposis/HHT)—more details of the genetics of HHT are provided in the following section. In the absence of HHT, PAVMs may develop sporadically, as a result of surgical treatments for several forms of complex cyanotic congenital heart disease^{4,5} or after trauma.⁶ Sporadic PAVMs are usually single, and multiple PAVMs should raise particular suspicion that there is underlying HHT.^{3,7,8}

Hereditary Hemorrhagic Telangiectasia

HHT is a disorder of vascular development inherited as an autosomal dominant trait. Careful epidemiologic studies reveal a true incidence of 1 in 5000 to 8000 in France, Denmark, and Japan⁹⁻¹¹; The condition is subject to underreporting in men, lower socioeconomic groups and geographical areas.¹² Higher prevalences are described in isolated communities.^{9,13} PAVMs detected on chest CT affect at least 50% of HHT patients¹⁴ and are particularly common in *HHT type 1* (HHT1), with 85% of *ENG* mutation carriers demonstrating R-L shunts on contrast echocardiography.¹⁵

Figure 61-1 Macroscopic right lower lobe pulmonary arteriovenous malformations (PAVMs) before (A) and after (B) embolization. Note embolization coils and restored perfusion of pulmonary arterial branches in **B**. Similar PAVMs were present in the left lung. Embolization over an 18-month period reduced the right-to-left shunt from 32% to 3% and increased the arterial oxygen saturation from 78% to 92% at rest.

Figure 61-2 Diffuse small pulmonary arteriovenous malformations in a patient with a right-to-left shunt greater than 30% following maximal embolization. The patient declined transplantation; arterial oxygen saturation (erect) was unchanged at 78% to 79% over the next 25 years.

Clinical Features and Diagnosis. Most individuals with HHT have nosebleeds, but are otherwise often minimally symptomatic. Telangiectasias increase with age: by age 16 years, 71% of individuals will have developed some sign of HHT, increasing to more than 90% by age 40 years.^{3,16}

To permit a high level of clinical suspicion without leading to overdiagnosis, international consensus diagnostic criteria were developed based on four findings: (1) spontaneous recurrent nosebleeds, (2) mucocutaneous telangiectasias, (3) visceral involvement, and (4) an affected first-degree relative (Table 61-2).¹⁷ When three criteria are present, “definite HHT” can be diagnosed; with two criteria, most commonly family history and nosebleeds, “suspected

Table 61-1 Historical Features of Untreated Pulmonary Arteriovenous Malformations

	Mean (%)	Range (%)	Comment
RESPIRATORY			
Asymptomatic	49	25–58	Increasing with screening
Dyspnea	50	27–71	Decreasing with screening
Chest pain	12	6–18	Rarely due to PAVM
Hemoptysis	11	4–18	
Hemothorax	1	0–2	
Cyanosis	27	9–73	Decreasing with screening
Clubbing	28	6–68	Decreasing with screening
Bruit	31	3–58	Decreasing with screening
CENTRAL NERVOUS SYSTEM			
Cerebral abscess	13	0–25	
CVA/TIA	27	11–55	
CVA	14	9–18	>50% with CT/MR infarcts
TIA	22	6–36	
Migraine	45	38–57	

CVA, cerebrovascular accident; TIA, transient ischemic attack.
Data as commonly cited based on cases published 1948–1998.²

Table 61-2 Clinical Features of Hereditary Hemorrhagic Telangiectasia

Criteria	Approximate Frequency (%)	Comment
Epistaxes (nose bleeds)	90	
Mucocutaneous telangiectasia	80	
Gastrointestinal bleeding	25	
Pulmonary AVMs	~50	Dependent on genotype
Hepatic AVMs	30–70	Dependent on genotype
Cerebral AVMs	<10	
Spinal AVMs	<1	

AVMs, arteriovenous malformations (may also arise in sites not listed above, such as pancreas).

HHT” is diagnosed. With only one criterion, typically spontaneous nosebleeds, in a patient with neither a family history nor a first-degree relative of an HHT patient, and with no signs of the disease, the diagnosis of HHT is “unlikely.” A crucial issue for families (and medical practitioners) is that no child of a patient with HHT can be informed that he or she does not have HHT, unless the child has had a molecular diagnosis that demonstrates that he or she has not inherited the HHT-causing gene mutation for that family.

Genetics and Pathogenesis. HHT is a genetically heterogeneous condition. Three disease-associated genes have been identified. HHT1 is caused by mutations in *ENG*, encoding endoglin,¹⁸ and *HHT type 2* (HHT2) by mutations in *ACVRL1*, encoding *activin receptor-like kinase* (ALK-1).¹⁹ More rarely, mutations in *SMAD4* cause HHT, usually in association with juvenile polyposis/HHT.²⁰ An HHT-like syndrome is caused by mutations in the gene coding for *bone morphogenetic protein* (BMP) 9.²¹ There are at least two further unidentified genes that can cause classic HHT, that is, *HHT3* on chromosome 5q between *D5S2011* and *D5S2490* and *HHT4* on chromosome 7p between *D7S2252* and *D7S510*.^{22,23}

A body of evidence indicates that HHT mutations result in a nonfunctional allele and haploinsufficiency, which leads to a lack of sufficient protein for normal function. The most obvious mutations that will fail to generate a protein include entire gene deletions, start codon mutations, and mutations with no detectable mutant RNA. In addition, the majority of mutations reported on the HHT mutation database lead to premature termination codons, indicating that the mutated RNA species will undergo nonsense-mediated decay.²⁴ Although there have been suggestions that the telangiectasias/AVMs may develop at sites where there was a genetic “second hit,” it is believed that in most, if not all cases, HHT results from haploinsufficiency.

Phenotype-Genotype Correlations. Pulmonary AVMs are more common in patients with either HHT1 (*ENG*) or juvenile polyposis/HHT (*SMAD4*) than in HHT2 (*ACVRL1* mutations).²⁵⁻²⁹ A characteristic finding is that different members of the same HHT family display different patterns of disease. Recent data have identified a modifier gene that makes PAVMs more likely.³⁰ Although there was an initial suggestion that overall severity of disease is greater in HHT1 than HHT2,²⁹ this study predated the recognition of pulmonary hypertension (see later) and, in a later series, there was no difference in 90-month mortality.²⁵

Cellular Basis. The genes mutated in HHT encode proteins that mediate signaling by the *transforming growth factor-β* (TGF-β) superfamily. Superfamily ligands such as TGF-βs, activins, and BMPs affect cellular growth and differentiation through signal transduction cascades from transmembrane receptor complexes. Endoglin is a relatively endothelial-specific co-receptor for multiple receptor complexes of the TGF-β superfamily.^{31,32} ALK-1 represents an endothelial-specific type I receptor that structurally and mechanistically belongs to the BMP branch of type I receptors.³³ ALK-1 can associate with at least two type II receptors, BMPRII and TβRII.³⁴ In turn, TβRII can associate with

two different TGF-β type I receptors in endothelial cells (TβRI [also known as ALK-5] or ALK-1), activating different Smad pathways, and apparently resulting in opposing endothelial cell responses in terms of proliferation, migration, and proangiogenic or antiangiogenic gene expression.³⁴⁻³⁸ Recent HHT concepts include the “balance hypothesis,” whereby the HHT mutations modify the predominant endothelial TGF-β type I receptor, Smad pathway, and ultimately endothelial cell response³⁵⁻³⁸; and models incorporating BMP9 and BMP10, which are specific ALK-1 ligands that can also bind endoglin.³⁹⁻⁴⁴ The likelihood of BMP9 being the ligand contributing to HHT pathogenesis increased with the recent identification of an HHT-like syndrome caused by BMP9 mutations.²¹ How the disease gene mutations lead to the vascular pathology has proved difficult to unravel. Attention now focuses on aberrant vascular responses to injury-induced angiogenic stimuli; in this setting, the mutated genes in HHT appear to result in the inability of a blood vessel to mature appropriately.⁴⁵⁻⁴⁸

Cavopulmonary Shunts. In non-HHT patients, PAVMs commonly develop in those who have undergone surgical treatments of several forms of complex cyanotic congenital heart disease resulting in anastomoses between the *superior vena cava* (SVC) and *inferior vena cava* (IVC) and the pulmonary arteries.⁴ In the Glenn anastomosis, the SVC is redirected to provide the venous blood flow for the pulmonary arteries. Using angiography, PAVMs were detected in 31% of patients undergoing classic Glenn anastomoses after a mean follow-up of 6.8 years.⁴

The incidence of PAVMs increases substantially if microscopic AVMs detectable by contrast echocardiography are included⁴⁹; moreover, microscopic arteriovenous shunting may develop within 2 hours of the procedure.⁵⁰ Some have suggested that, following superior bidirectional cavopulmonary anastomosis (Kawashima procedure, in which almost all venous blood except the hepatic venous blood flow is redirected to the pulmonary arteries), the development of functional intrapulmonary shunts may be universal. Contrast-enhanced *magnetic resonance* (MR) angiography is emerging as a useful assessment modality for these patients.⁵¹

The key etiologic feature appears to be the route taken by hepatic venous flow, because PAVMs develop in the lung that receives no or minimal hepatic venous return, and regress if hepatic venous blood flow to the lung is restored.^{5,52-54} Serum levels of endostatin, a potent inhibitor of angiogenesis produced by the liver, drop after Glenn procedures ($n = 17$; 4.42 vs. 3.34 ng/mL; $P < 0.001$) (in which only SVC, not IVC, blood is directed to the lungs), but not after Fontan procedures ($n = 13$) (in which both SVC and IVC blood is directed to the lungs).⁵⁵ Because a decrease in endostatin may promote angiogenesis, the authors propose that the potential role of endostatin in the pathogenesis of PAVMs warrants further study.⁵⁵

PATHOPHYSIOLOGY

Anatomic Basis

Both macroscopic (see Fig. 61-1) and microscopic or diffuse PAVMs are recognized. In simple PAVMs, an aneurysmal

Figure 61-3 Histopathology of a pulmonary arteriovenous malformation that ruptured in pregnancy. Note site of rupture (narrow arrows) at lower border and region of endothelial intimal fibrous proliferation (thick arrow). (Shovlin CL, Sodhi V, McCarthy A, et al: Estimates of maternal risks of pregnancy for women with hereditary haemorrhagic telangiectasia: suggested approach for obstetrics services. *Br J Obstet Gynaecol* 115:1108–1115, 2008.)

venous sac is supplied by a single artery and drained by a single vein. In complex PAVMs, a group of venous sacs are supplied by multiple vessels arising from adjacent segmental or subsegmental pulmonary artery branches and draining into multiple veins.^{56–58} They may be discrete (which is more common), or diffuse when a single segment,⁵⁹ or every segment of one or more lobes⁶⁰ are involved. The sacs are characterized by walls of varying degrees of thickness, even over relatively short segments, with disorganized adventitia. Medial thinning is observed, but areas of focal thickening with abundant elastin tissue and a varying contribution of smooth muscle cells are also prominent (Fig. 61-3).^{44,61}

PAVMs occasionally develop in the prenatal or perinatal period, and are present during childhood. In a series of 44 children (mean age 10.3 years, range 1 to 18 years), 20 (45%) had PAVMs detected by screening studies.⁶² PAVMs increase in size during puberty, in female patients during pregnancy,⁶³ and in the presence of pulmonary venous hypertension secondary to mitral stenosis or left ventricular dysfunction.⁶⁴ Pulmonary emboli can lead to temporary regression,⁶⁵ and on rare occasions, permanent spontaneous regression has been described.⁶⁶

Physiologic Attributes at Rest

Right-to-Left Shunt. PAVMs provide an anatomic R-L shunt, with the proportion of the cardiac output using the shunt pathways (shunt fraction) varying widely but reaching up to 60% in severe cases. In early series,^{67–71} mean R-L shunt fractions were generally higher (23% to 38%) than was found in later reports (8% to 13%),^{72–74} in which earlier diagnosis had taken place owing to more energetic screening procedures. Arterial PO_2 and arterial oxygen saturation (SO_2) are inversely related to the size of the R-L shunt fraction.^{75,76} The contribution of ventilation-perfusion mismatch to arterial hypoxemia in PAVMs is small, except in the occasional patient with significant coexisting lung disease.

Compensations for hypoxemia are usually highly successful. Chronic adaptations include secondary erythrocytosis which preserves the arterial oxygen content.^{77–79} Acute responses utilize increased cardiac output through heart rate (for acute falls in arterial oxygen content, e.g., on standing),⁷⁸ and stroke volume.^{67,80} which can preserve the oxygen pulse (oxygen utilized/delivered per heart beat) at rest and on exercise.⁸⁰

Pulmonary Hemodynamics. The absence of a microvascular network of capillary vessels in the PAVMs means that the pulmonary vascular resistance (PVR) of PAVMs is less than that of the surrounding normal lung. The effect on the overall PVR depends on the proportion of the cardiac output flowing through the shunt channels. In one study of eight patients with PAVM with large R-L shunt fractions (mean $31\% \pm 4\%$ [standard error]), mean PVR was 0.33 ± 0.08 mm Hg/L/min (normal 0.5 to 1.3 mm Hg/L/min) and pulmonary artery pressure (PPA) was 14 ± 0.6 mm Hg (normal 12 to 16 mm Hg), respectively.⁶⁷ PVR was low, despite normal PPA, because total pulmonary blood flow was high (8 ± 0.8 L/min [160% of predicted]). In later studies with smaller mean R-L shunt fractions (8.5% to 11.5%), mean pulmonary systolic and diastolic pressures have been in the normal range,^{72,74,81} and recent studies have focused on the occasional presence of coexisting pulmonary hypertension^{82–89} (see section on HHT-related pulmonary hypertension).

Pulmonary Function. Vital capacity is generally normal.^{68–72} There is no airflow obstruction unless a second pathology such as asthma or COPD is present.^{68,77} With large R-L shunts (>20%), the carbon monoxide diffusing capacity (DL_{CO}) is often moderately reduced (71% to 78%),^{68,71} but in the majority of patients with less R-L shunting, DL_{CO} is equal to or greater than 90% of predicted (interquartile range, 76% to 100%).⁷² Patients with the lowest DL_{CO} values generally have widespread and small vascular malformations.

Physiologic Consequences of Posture and Exercise

Posture. PAVMs are more common in the lower lobes than in the upper lobes.^{8,68} Hence, for gravitational reasons, the shunt fraction tends to increase when patients stand up; in one study, R-L shunt increased from 28.7% to 39% in eight patients upon standing.⁶⁹ Accordingly, arterial oxygen saturation falls. In 257 patients reported recently, 75 (29%) demonstrated orthodeoxia with an oxygen saturation fall of at least 2% on standing.⁷⁸ This was accompanied by an orthostatic tachycardia, with an age-adjusted pulse rise of 0.79 min^{-1} per 1% arterial SO_2 fall ($P < 0.001$).⁷⁸

Exercise. In the healthy lung during exercise, PVR falls to half its value at rest, attributed to dilation and recruitment of vessels in the pulmonary capillary bed. The effects of exercise on pulmonary hemodynamics in a PAVM-affected patient depend on the change in vascular resistance through the shunt channels in relation to the change in the resistance of the normal channels. In one group of eight patients with PAVM with severe arterial hypoxemia on exercise (arterial oxygen saturation $74\% \pm 3\%$), there was an

excessive increase in total pulmonary blood flow (142% of predicted) in relation to the observed *oxygen consumption* ($\dot{V}O_2$), resulting, in turn, in higher than predicted tissue oxygen delivery on exercise.⁶⁷

The change in arterial oxygen saturation from rest to exercise depends both on the change in the shunt fraction and the fall in mixed venous oxygen saturation on exercise. For patients with PAVM, overall, the fall in arterial oxygen saturation (rest to exercise) averaged 6% for mean shunts greater than 30%,^{67,70} 3% for mean shunts of 20% to 25%,^{68,70,72} and 1% to 2% for mean shunts less than 12%.⁷²

Overall, gas-exchange efficiency in terms of the *ventilatory equivalent* ($\dot{V}E/\dot{V}O_2$) is abnormally high on exercise; observed values are directly related to the exercise R-L shunt and inversely related to exercise arterial oxygen saturation.^{67,80}

Work capacity is well preserved in PAVM patients, even when arterial oxygen saturation on exercise is less than 80%.^{72,80} The adaptive responses are lost following correction of hypoxemia.^{77,80,90} In a recent study, despite higher arterial SO_2 , treated patients achieved similar work rates and similar peak oxygen consumption.⁸⁰ It is noteworthy that treated patients reset to virtually identical peak oxygen pulses and, in many cases, to the same point on the peak oxygen pulse/work-rate plot.⁸⁰

Pulmonary Hypertension

Pulmonary hypertension has been recognized in a number of patients with HHT.⁸¹⁻⁸⁹ The causes of pulmonary hypertension in HHT are diverse, as in the normal population. Two forms of pulmonary hypertension predominate in HHT: true pulmonary hypertension and postcapillary pulmonary hypertension seen in the context of high-output cardiac failure secondary to hepatic AVMs, a potentially reversible form of pulmonary hypertension. Mixed pictures are also observed.⁸¹ The frequency of pulmonary hypertension and hepatic AVMs differs with HHT genotype: pulmonary hypertension, and hepatic AVMs are more common in HHT type 2—due to *ACVRL1* mutations—than in other forms of HHT.^{86,88}

The overall prevalence of pulmonary hypertension in HHT is relatively low. Catheter-based studies in a group of 143 PAVM/HHT patients undergoing PAVM embolization, identified values for mean PPA as 13 (11 to 16) mm Hg, compared to normal values of 7 to 19 mm Hg.⁸¹ While PPA mean exceeded 20 mm Hg in 9 of 143 patients (6%), only 2 referred from services other than specialized pulmonary hypertension units had mean PPA values exceeding 35 mm Hg.⁸⁹ In one echocardiographic study of 68 HHT patients (ages 19 to 84 [mean 51] years), estimated systolic PPA values (40 to 58 mm Hg) were above the normal range in 9 (20.5%).⁸⁴ A separate study suggested pulmonary hypertension rates were higher (>30%) in hospitalized than in nonhospitalized patients.⁸⁹

CLINICAL FEATURES

Respiratory Symptoms

Dyspnea. Dyspnea is the respiratory symptom most commonly reported by PAVM patients, but this is present in less than 50% of all cases (see Table 61-1) and may not be

appreciated until after the condition has been treated. In one series of 219 consecutive patients, symptomatic dyspnea was generally only present when resting arterial oxygen saturations were less than 80%.^{74,81} Three subsequent studies showed no relationship between arterial SO_2 and dyspnea as self-reported (N = 165, arterial SO_2 78.5%-99%);⁷⁷ by Borg scales during cardiopulmonary exercise testing (N = 21, arterial SO_2 80%-96%);⁷⁸ or as self-reported during flight (N = 99; arterial SO_2 85%-99%).⁹¹ None of 75 consecutive patients demonstrating orthodeoxia reported platypnea (dyspnea on standing).⁷⁸

Hemoptysis. The fragile vessels in HHT should be more prone to hemorrhage than normal pulmonary vessels but, surprisingly, hemoptysis and hemothorax are relatively rare features for PAVMs (see Table 61-1), with two important exceptions: (1) with a spontaneous or postembolization systemic arterial blood supply to PAVM sacs,^{57,59,92} and (2) with pregnancy-associated changes.^{61,63} Both conditions place patients at higher risk of hemorrhage from PAVMs, which may be massive and life-threatening.

Chest Pain. Pleuritic chest pain of uncertain etiology may be described in up to 10% of PAVM patients (see Table 61-1). PAVM associations are likely to be overestimated, however, in series that do not correct for ascertainment bias of incidental PAVM detection following protocol-driven CT scans for suspected pulmonary embolism.

Strokes and Cerebral Abscess

PAVMs pose a substantial risk to patients because of paradoxical emboli leading to cerebral abscess or ischemic stroke,⁹³ as repeatedly reported in high proportions of patients in historical series (see Table 61-1).^{7,94,95} In more recent series, in which correction was made for ascertainment bias (i.e., diagnosis of PAVMs because of the presentation with stroke/abscess), rates for cerebral abscess were 7.8% to 9%^{74,96} and for ischemic stroke were 11.3% (Fig. 61-4).⁷⁴ Relative risks compared to control populations were particularly high in young adults.⁷⁴

Small studies using univariate analyses had suggested that neurologic complications were more common in patients with more severe PAVMs, defined by either PAVM size⁹⁷ or diffuse characteristics.⁵⁹ Paradoxical embolic events are more common in patients with the higher grade contrast echocardiography shunts that are more likely to be associated with visible PAVMs seen on CT.⁹⁸ Once PAVMs are sufficiently large for CT detection, or grade 3 shunts, there is little evidence that stroke risk is substantially influenced by further increase in shunt size^{74,76} or by conventional stroke risk factors (smoking, hypertension, diabetes mellitus, atrial fibrillation, and hypercholesterolemia).^{74,76} Ischemic strokes only occasionally develop following venous thromboemboli.^{65,74,76}

The strongest risk factor for ischemic stroke in the presence of PAVMs appears to be iron deficiency, with the risk of stroke falling by 0.96 for every 1 μ mol increase in serum iron.⁷⁶ Exuberant platelet aggregation to 5HT was proposed as a mechanistic link.⁷⁶ Two overlapping cohorts demonstrated that ischemic strokes were less common in patients with higher mean PPA^{74,76} and, once adjusted for PPA, marginally more frequent in patients with lower arterial SO_2 .⁷⁶

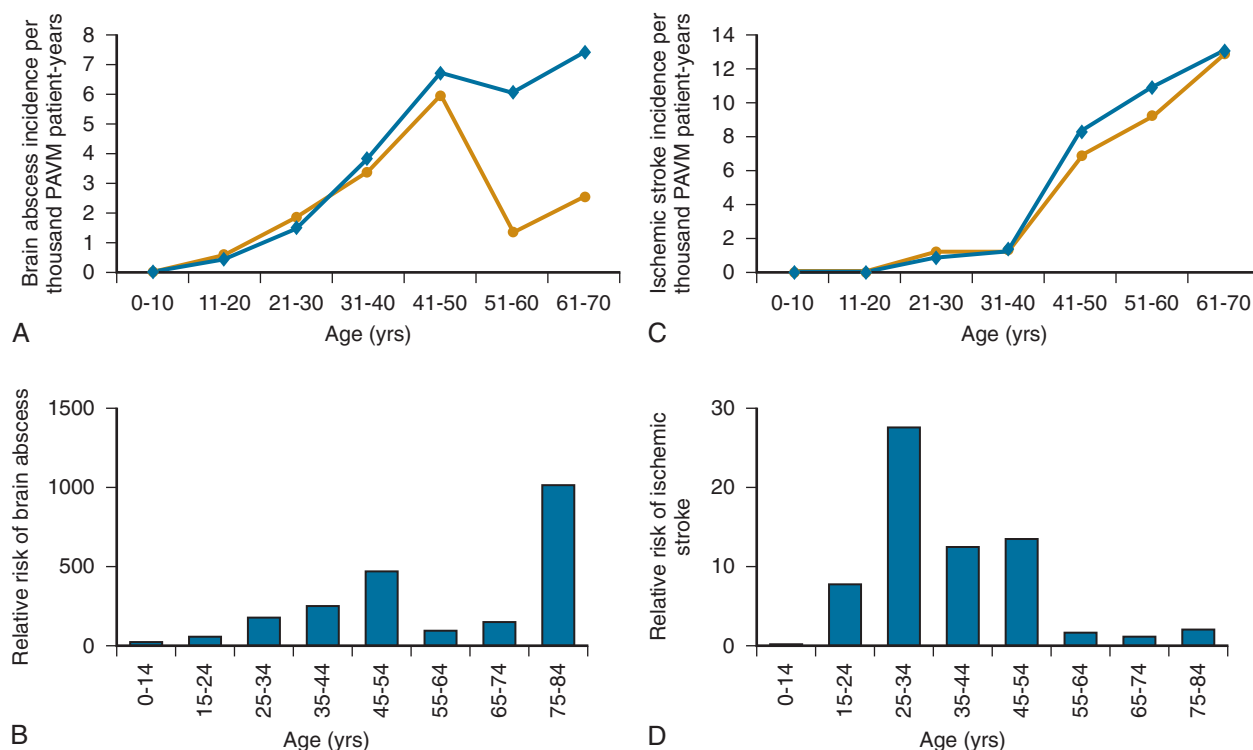

Figure 61-4 Age-specific incidence rates and relative risks of brain abscess and ischemic stroke. Age-specific incidence rates of brain abscess (A) and ischemic stroke (C) for all patients (diamonds/blue lines), and patients excluding ascertainment bias (solid circles/brown lines). Relative risk (fold increase) for brain abscess (B) and ischemic stroke (D) for pulmonary arteriovenous malformations patients, excluding individuals who presented because of their stroke/abscess. Brain abscess and stroke rates are compared to the general population. (Redrawn from Shovlin CL, Jackson JE, Bamford KB, et al: Primary determinants of ischaemic stroke and cerebral abscess are unrelated to severity of pulmonary arteriovenous malformations in HHT. *Thorax* 63:259–266, 2008.)

For cerebral abscess, there were strong associations with male gender and dental microorganisms⁷⁴; once adjusted for male gender, there was also an association between lower arterial SO_2 and brain abscess.⁷⁴

Other Neurologic Events

An excess of migraine was first noted in HHT populations.^{99,100} Multiple studies have now demonstrated that the risk of migraine in patients with HHT is approximately doubled if they have PAVMs,¹⁰¹⁻¹⁰⁶ and there is evidence that migraines improve following PAVM treatment.^{102,104} The theoretical basis for scuba diving–related stroke risks is discussed elsewhere.¹⁰⁷

Pregnancy

Pregnancy carries specific hazards for women with PAVMs,^{61,63,108-111} including for women who have been treated for PAVMs.⁶¹ In a study of 484 pregnancies in women with HHT and PAVMs, 1% of pregnancies (95% CI, 0.13% to 1.9%) resulted in maternal death.⁶¹ Maternal deaths have been attributed to PAVM hemorrhage (1% of pregnancies; 95% CI, 0.1% to 1.9%),⁶¹ cerebral hemorrhage,⁶¹ and pulmonary emboli. In four women, the severity of PAVMs associated with life-threatening hemorrhage could be evaluated: two had small PAVMs associated with normal arterial oxygen saturations and near-normal R-L shunts; none had evidence of pulmonary hypertension.⁶¹ In women experiencing a life-threatening event, prior awareness of HHT or of a diagnosis of PAVM was associated with improved survival ($P = 0.04$).⁶¹

DIAGNOSIS

Classic PAVM cases with large R-L shunts are easy to diagnose because of cyanosis, clubbing, a vascular bruit, and characteristic chest radiographs displaying lobulated masses and dilated feeding arteries and draining veins. Detection of smaller PAVMs, however, often requires a high degree of clinical suspicion.

Imaging

The classic appearance of a PAVM on chest radiography, chest CT, and catheter pulmonary angiography consists of a circumscribed, rounded, soft tissue nodule of any size associated with enlarged feeding and draining vessels (see Fig. 61-1, eFig. 61-1). Complex PAVMs are generally less well defined, although rounded nodular elements associated with prominent feeding arteries and draining veins are usually evident (eFig. 61-2). Diffuse lesions involving whole lung segments are seen as an area of generalized increased opacity with marked prominence of vascular markings but no discrete nodules. Before 2007, there was widespread opinion that the only PAVMs of clinical significance had feeding artery sizes larger than 3 mm, and the goals of many screening programs reflected this. Data presented in this era were that the chest radiograph was abnormal in 60% to 90% of instances.^{68,72,112} It is anticipated that the frequency of positive standard frontal radiographs will fall further as smaller PAVMs are sought (eFig. 61-3), in keeping with the recognition that these are an important cause of neurologic complications.^{74,76,97}

Figure 61-5 Contrast echocardiography showing different grades of left ventricular opacification. The grades shown are minimal (A), moderate (B), extensive (C), and extensive (D) with endocardial definition. The likelihood of detecting a pulmonary arteriovenous malformation on chest CT increases with higher grades of abnormality. (From Parra JA, Bueno J, Zarauza J, et al: Graded contrast echocardiography in pulmonary arteriovenous malformations. *Eur Respir J* 35:1281–1285, 2010. Reproduced with permission of the European Respiratory Society.)

Chest CT, without intravenous contrast medium, usually demonstrates the anatomy of PAVMs and their feeding vessels^{56,57,113} (see eFigs. 61-1C, 61-2C-F, 61-3C, and 61-4C, D, G, and H; see also eFig. 18-15); the radiation burden is greatly lessened and the resolution improved by the use of newer multislice CT protocols, which limit x-ray exposure to a single short breath-hold scan and which allow elegant multiplanar reconstructions of the images (see eFig. 18-15). MR imaging has been less effective than CT or pulmonary angiography in detecting small PAVMs with rapid blood flow.¹¹⁴ Methodology, though, is improving,¹¹⁵ and this modality does have the advantage that it provides no radiation exposure. But the frequency of its use may not increase as attention focuses on identification of the small CT-evident, yet clinically significant PAVMs (see also Chapter 18). Where there are difficulties with interpretation of dilated and apparent vascular structures, confirmation of R-L shunting may be helpful. A recent pictorial review highlights anatomic PAVM “mimics.”⁵⁸

Measurement of Right-to-Left Shunt

Classically, R-L shunts were calculated by measuring the arterial PO_2 in a patient breathing 100% oxygen, and by measuring ^{99m}Tc -macroaggregated albumin distribution to lung and kidney. R-L shunt measurements by either of these methods may confirm a diagnosis suspected on clinical grounds and provide useful follow-up data, but

neither is now generally used for diagnosis or follow-up of PAVMs.

Contrast Echocardiography. The method of *contrast echocardiography* (CE; synonym “echo-bubble”) demonstrates intrapulmonary shunts by tracing the circulatory transit of microbubbles generated by intravenously injected echocontrast material. Microbubbles seen in the left heart should therefore be the result of an R-L shunt, either cardiac (most commonly a patent foramen ovale) or pulmonary. Typically, with an intrapulmonary shunt such as a PAVM, the number of bubbles in the left heart increases after a matter of seconds (Fig. 61-5 and Video 61-1). The entry of bubbles is not affected by the cardiac cycle or respiration, and though influenced slightly by a Valsalva maneuver, this is in a more subtle manner to the changes observed with a patent foramen ovale.

CE consistently detects more intrapulmonary R-L shunting in HHT patients than any other PAVM screening modality.¹¹⁶⁻¹²⁵ False-negative results can result, but it was early reports demonstrating high sensitivity with no attendant radiation burden that led to current guidelines recommendations to use CE as the first-line method for PAVM screening.¹¹⁸

Presence of a positive shunt by echocardiography does not imply that a macroscopic PAVM will be found. Appreciable proportions of the general population exhibit intrapulmonary shunting; in one early study, intrapulmonary

shunts were found in 5 of 19 healthy subjects in whom contrast was injected directly into the pulmonary artery, thereby bypassing any intracardiac shunt.¹¹⁹ More recent studies using CE documented shunting in 6% to 7% of control subjects at rest,¹²⁰ rising to as high as 90% on exercise.¹²¹ Previous studies demonstrated a high frequency of false-positive results in which PAVMs were not identified by subsequent angiography, considered to be the “gold standard” for detection of PAVMs.^{112,119,123} For patients with endoglin mutations, a positive CE study only provided a positive predictive value for a treatable PAVM of 36.3%.¹⁵

Reassuringly, in the HHT-based research studies, no treatable PAVMs were found in individuals with negative CE studies, although these accounted on average for only 39% of screened individuals.¹¹⁹⁻¹²⁵ In one study of patients stratified by HHT mutations, 85% of those with endoglin mutations and 35% of those with *ACVRL1* mutations had a positive shunt by CE.¹⁵

Specialist groups have incorporated grading systems to examine whether clinically significant PAVMs could be excluded by low-grade positive CE studies (see Fig. 61-5). The broad grades of CE shunt severity range from grade 1 (found in at least 7% to 8% of the general population^{15,120,121}), to grades 3 and 4, which are more frequently associated with visible PAVMs seen on CT (see Fig. 61-3) and neurologic complications.⁹⁸ In a recent two-center study of 1038 patients undergoing PAVM screening, 530 (51%) had a positive CE shunt, but there was no enhanced stroke risk in patients with grade 1 shunts (<30 microbubbles per frame).⁹⁸ For patients with grade 2 (30 to 100 microbubbles per frame) or grade 3 (>100 microbubbles per frame) shunts, the odds ratios for cerebral ischemic event or brain abscess were 4.8 ($P = 0.03$) and 10.4 ($P = 0.002$), respectively.⁹⁸ In general, with increasing grade of abnormality on CE, the likelihood of finding a PAVM on CT and the risk of embolic events increase.

Screening Patients

The importance of screening programs for HHT is highlighted by the high proportions of patients with HHT/PAVM who are undiagnosed at the time of their PAVM-induced ischemic stroke or cerebral abscess (in one series, 66.7% and 64.3% respectively).⁷⁴

Screening modalities differ among PAVM centers, according to the expertise of the institution. Common to all programs are the policies of minimizing the radiation burden in an often young population and having a sensitive screen to detect all clinically significant and treatable PAVMs: the choice of study is usually chest CT or CE. With new generations of multislice chest CT scanners, diagnosis of clinically significant PAVMs can be made efficiently and quickly using a single-breath scan. Many specialized PAVM units with extensive CE expertise use CE as a first-line screen for PAVMs, reserving the radiation exposure of CT for patients with a positive CE shunt and, in some cases, with a CE shunt of a particular severity. At other institutions, CE is not used routinely because most CE studies yield positive results (see earlier discussion) and because of uncertainty about whether the published data provide sufficient confidence to withhold a CT, given the variability of CE-detected shunts with posture, Valsalva maneuvers, and repeat studies.¹⁰⁷ Some centers use pulmonary angiography as a tool to

confirm the diagnosis but, to reduce the radiation burden, we prefer to restrict angiography to therapeutic embolization sessions.

MANAGEMENT

A recent Cochrane database review concluded that randomized control trials of embolization of PAVMs have not been performed owing to ethical considerations, but that accumulated data from observational studies suggest embolization reduces morbidity.¹²⁶

Embolization

Percutaneous transcatheter embolization, which was introduced in 1978,^{127,128} is now the treatment of choice for the vast majority of patients.^{57,66,113,129-140} Vessels are considered for embolization when they are amenable to treatment, usually greater than 2 to 3 mm in diameter. The technique of embolization at our institution has been described previously.⁶⁶ The procedure is performed with antibiotic prophylaxis administered as a single dose 1 hour before angiography. Via a femoral venous approach, under local anaesthesia, pulmonary angiography is first performed using a pigtail catheter, which is then exchanged for a long 6-French straight sheath and a 5-French catheter combination. The feeding vessels to the PAVMs are selectively catheterized in turn and are occluded at the junction between the artery and venous sac with detachable metallic plugs and/or coils (eFigs. 61-4C-H and 61-5).

Amplatzer vascular plugs are rapidly becoming the preferred agent for PAVM embolization.¹³¹⁻¹³³ They have a number of important advantages over coils, including the ability to occlude the feeding vessel to a PAVM at the neck of the venous sac, the ability to occlude large diameter feeding arteries (measuring up to 1.2 mm in diameter) with single Amplatzer vascular plugs so that a larger number of PAVMs can be embolized in a single session (reducing radiation exposure), and the ability to occlude over a shorter length of vessel, thereby reducing the likelihood of occluding vessels supplying normal lung.¹⁰⁷

Long-Term Outcome. Anatomic long-term results of transcatheter embolization have been evaluated by several centers. After embolization, residual shunting through untreatable (<2 to 3 mm diameter) arterial feeding vessels is common (see eFig. 61-4H). Additionally, treated PAVMs may recanalize and/or reperfuse.^{57,113,132-135,138} Factors associated with reperfusion include a low number of coils, oversized coils, proximal placement of coils, and altered pulmonary hemodynamics (development of pulmonary hypertension or presence of hepatic AVMs).¹³⁴⁻¹³⁷ In one series of 192 PAVM patients in whom feeding arteries less than 3 mm in diameter were embolized,⁷⁴ 70% had residual disease, a finding supported by other studies (eTable 61-1).^{104,129,130} It has been recommended to use CT scans for 6-month and 1-to-3-years follow-up,¹¹⁸ but the recently documented radiation burden¹³⁷ calls this into question: In one series of 246 PAVM patients with HHT, CT scans accounted for 46% of the mean *cumulative effective dose* (CED).

Physiologic Outcome. Substantial improvement in oxygen saturation is the rule for patients with preembolization

[§]Arterial PO₂ values breathing 100% oxygen.

hypoxemia (see eTable 61-1),^{71,77,81,129,138-140} with little effect on other pulmonary function measurements.^{68,72,75} Compensatory mechanisms reset; falls in hemoglobin restore arterial oxygen content to pre-embolization levels.⁷⁷ Stroke volume and cardiac output also fall after treatment of PAVMs,⁹⁰ and oxygen consumption at peak exercise is unchanged.⁸⁰

Clinical Outcome. Unsurprisingly exercise capacity, which is often relatively unimpaired before embolization,⁸¹ only improves in a subgroup of patients.⁷⁵ Concurrent cardiopulmonary disease was a predictor of improvement in one series of 98 treated patients.⁷⁷ Several studies have now demonstrated the clinical efficacy of embolization in improving stroke/abscess risk⁷⁴ and reducing the prevalence of migraine.^{102,104}

Risks of Embolization

In expert hands, embolization is efficacious and complications are rare, even though the procedure is not without risk. Successive series highlight a learning curve, and smaller series have higher complication rates. The most common complication is transient pleurisy in up to 10% of patients, particularly those with peripheral PAVMs. Higher rates are seen in patients with diffuse PAVMs.⁵⁹ The mechanism for the pleurisy is unknown, but it appears unrelated to pulmonary infarction.^{68,72} Angina is rare and is attributed to transient air bubble emboli, and has been reduced by technical advances reported in later series. There are occasional reports of long-term neurologic complications after embolization due to paradoxical emboli.¹⁴¹

Radiation Exposure. New data demonstrate that currently employed protocols can result in levels of radiation exposure that would be classified as harmful.¹³⁷ In a single center study of 246 PAVM patients (53 years mean age), the mean CED over an 11-year period was 51.7 mSv, and CED exceeded 100 mSv in 26 patients (11%).¹³⁷ Interventional procedures accounted for 51% of the CED.¹³⁷

Development of Systemic Arterial Supply. The risk of massive hemoptysis from PAVM sacs that persist after embolization and that acquire a systemic arterial collateral blood supply was first highlighted in a small series published in 1998.⁹² In view of the known importance of pulmonary-bronchial communications (see Systemic-to-Pulmonary Vascular Communications), systemic collaterals might be expected to develop to supply an area of the pulmonary capillary bed that had lost its pulmonary arterial supply as a result of embolization. Systemic supply is only of consequence if the fragile PAVM sac persists. None of the patients in Brillet and coworkers' series¹⁴² experienced hemoptysis, in contrast to the majority of those in a smaller series.⁹² To reduce the risk for development of systemic arterial collateral supply to any persistent sac, standard practice is to place embolization devices as close as possible to the neck of the malformation (see eFigs. 61-4C-H and 61-5).^{107,132} This is particularly difficult in patients with diffuse PAVMs, in whom sac persistence is inevitable. Expert institutions differ in the degree to which such PAVMs are embolized. At our institution, more limited embolization is undertaken and in the presence of ongoing neurologic symptoms

or hemoptysis, surgical resection is considered. Other approaches include dense packing of the most severely involved segmental arteries.⁵⁹

Development of Pulmonary Hypertension. PAVM embolization may be expected to elevate PPA, because PAVMs provide low-resistance pathways for pulmonary blood flow. Individual cases in which PPA increased both after embolization and after surgical resection are reported.^{71,81,143-147} In one series of 35 patients, there was no evidence of a sustained or acute change in PPA in the majority of patients and, in half, embolization led to a fall in PPA.⁸¹

Should embolization of PAVMs be performed in patients with severe preexisting pulmonary hypertension? This question was specifically addressed in light of lower stroke risk^{74,147} and data indicating that test balloon occlusion did not predict subsequent rise in PPA following definitive embolization.⁸¹ The main indications for PAVM embolization are to reduce the risk of paradoxical embolic stroke/brain abscess and, for individuals with hypoxemia, to improve dyspnea and exercise tolerance. The authors concluded that, for patients with preexisting severe pulmonary hypertension, the risks of PAVM embolization generally outweigh potential benefits.^{81,147} It was recognized that the most difficult judgments relate to individuals with severe pulmonary hypertension and major hemoptysis.^{81,147} Additionally, it is now recognized that higher PPA is one of the predictors for symptomatic improvement post embolization.⁷⁷

Nonembolization Options

There are circumstances when PAVMs cannot be treated by embolization, with the most common reason being that the feeding artery is too small (<2 mm diameter).

Surgery. Surgery remained the treatment of choice until the 1980s but was never the ideal solution for the multiple PAVMs of HHT; more recently, however, surgery has been a useful adjunctive therapy for selected cases. There may be times when small PAVMs are single or sufficiently localized for thoracoscopic resection when embolization is not feasible. At our institution, and elsewhere,¹⁴⁸ elective surgical treatments are reserved for patients demonstrating ongoing ischemic strokes or transient ischemic attacks following maximal embolization. In emergency situations, particularly associated with massive hemoptysis, lobectomy or pneumonectomy may be appropriate.^{61,148,149}

Lung transplantation has been undertaken in a few patients with severe hypoxemia secondary to diffuse disease.¹⁵⁰⁻¹⁵² The long-term complications of untreated PAVMs, however, are likely in most cases to be less than transplantation-associated morbidity and mortality. The three patients with PAVM in our clinic (one male, two female) who elected not to proceed with transplantation—after discussion of the risks at two different transplantation centers—have since remained stable over 20, 22, and 25 years, and one patient has had three successful pregnancies. In a retrospective series of 36 patients with diffuse PAVMs for whom follow-up data were available for a mean of 8.5 years (range, 0.12 to 26 years), 24 of the 27 survivors were working or studying full time; one of the deaths was transplantation associated.⁵⁹

Medical Management

Dental Issues. For patients with PAVMs and HHT, owing to the strong link between oral bacteria and cerebral abscess, antibiotic prophylaxis before dental and surgical procedures was recommended based on the endocarditis paradigm.¹⁵³⁻¹⁵⁵ The evidence for an association between oral microorganisms and brain abscess has since been strengthened.^{74,156} American Heart Association¹⁵⁷ and British National Institute for Health and Care Excellence¹⁵⁸ guidelines indicate that antibiotic prophylaxis is no longer required for most patients with structural heart disease at risk for infective endocarditis. This has led to confusion among dentists and medical practitioners caring for patients with PAVM. A recent article exploring why PAVM/HHT patients do not fall into the groups considered by the guidelines provided recommendations to reduce the risk of dental bacteremias, including the use of antibiotic prophylaxis before dental procedures.¹⁵⁹

Pregnancy. In view of the risks of PAVM growth and rupture during pregnancy, it is recommended that female patients be advised to defer pregnancy pending formal PAVM assessment and treatment. Pregnancies should be managed with close liaison between obstetricians, pulmonologists, and interventional radiologists, using appropriate “high-risk” obstetric management strategies.⁶¹ Patients and their medical practitioners should be alerted to the possibility of hemoptysis or sudden severe dyspnea that requires urgent admission and management: embolization in the second and third trimesters is feasible.^{61,160} The question of whether PAVM embolization should be offered to asymptomatic pregnant women differs between countries; at our institution it is not performed.⁶¹

Thromboembolic Risks. The American Stroke Association recommends antiplatelet agents for secondary prevention of ischemic stroke in PAVM patients.⁹³ Antiplatelet therapy can be considered on a case-by-case basis for patients, even if there is underlying HHT.¹⁶¹ Venous thromboemboli are common, associated with conventional venous thromboembolism risk factors and iron deficiency,¹⁶² and both prophylaxis and treatment with anticoagulants may be required, even when HHT is present.¹⁶¹

SYSTEMIC-TO-PULMONARY VASCULAR COMMUNICATIONS

ANATOMY

Communications between the systemic and pulmonary circulations are part of normal anatomy, in that terminal branches of the bronchial microcirculation communicate with peripheral pulmonary artery branches (Fig. 61-6A). These vessels are functionally important in preventing lung infarction in the great majority of cases of pulmonary embolic disease. Their presence may be detected during specialized functional scans such as contrast-enhanced, time-resolved perfusion MR imaging of regions of the lung in which hypoxic pulmonary vasoconstriction reduces pulmonary arterial supply; late filling might reflect the systemic arterial component.¹⁶³ In the presence of chronic intrapul-

Figure 61-6 Catheter angiogram imaging of normal and abnormal bronchial circulations. **A**, Selective digital subtraction angiogram showing normal bronchial arteries. Normal peripheral pulmonary artery branches are opacified (arrows) via normal bronchopulmonary anastomoses. **B**, Digital subtraction descending aortogram in a patient with hemoptysis due to previous right apical tuberculosis. There is bronchial and nonbronchial systemic artery hypertrophy supplying the right upper zone, with retrograde opacification of the entire right upper lobe pulmonary artery (arrow) via enlarged bronchopulmonary anastomoses.

monary inflammatory disease, normal bronchopulmonary anastomoses enlarge considerably (Fig. 61-6B), increasing the perfusion pressure to the diseased lung, thereby increasing the likelihood of bleeding. Abnormal precapillary communications develop in multiple respiratory pathologies¹⁶⁴ especially when chronic inflammatory pulmonary disease is located peripherally and systemic supply is recruited transpleurally through dense inflammatory adhesions between the lung and the chest wall (eFig. 61-6 and Video 61-2). Direct communications between systemic arteries and the pulmonary circulation are also observed in several other settings (see later), such as when systemic arteries communicate with the pulmonary artery or its branch via the pulmonary ligament, which encloses the lung hilum. Intralobar sequestration (see Pulmonary Sequestration) is a developmental anomaly in which a systemic artery replaces a segmental pulmonary artery (see eFig. 18-18).

Adult (Acquired) Systemic-to-Pulmonary Communications

As noted, abnormally large systemic-to-pulmonary communications form part of the inflammatory response to the presence of chronically inflamed or necrotic lung tissue; the most frequent causes, according to Yoon and colleagues,¹⁶⁵ are pulmonary tuberculosis (usually chronic), aspergilloma (secondary to chronic sarcoidosis or tuberculosis), and bronchiectasis, including that caused by cystic fibrosis¹⁶⁶ (see Fig. 61-6B). Overlying pleural thickening provides transpleural access for systemic vessels arising from the intercostal (see eFig. 61-6), internal mammary, thyrocervical, axillary, and inferior phrenic arteries. For more proximal intrapulmonary disease, vascular hypertrophy and new vessel formation arise within the bronchial circulation.

Fetal and Perinatal Systemic-to-Pulmonary Artery Collaterals

During bronchial branching in the developing fetus, the dividing buds are supplied by a capillary plexus derived from the primitive aorta; this plexus later regresses as the growing lung advances and the developing pulmonary artery takes over. Between the 40th and 50th days of gestation, the lungs have a dual source of blood supply.^{166,167} Systemic-to-pulmonary artery collaterals arising from the proximal or distal part of the aortic arch persist in later gestation and were functional in 88 of 133 (66%) premature, very-low-birth-weight (<1500 g) infants, and declined with maturity, until, at 1 year of age, only 2 of the original 88 infants still had collaterals.¹⁶⁸

When present postnatally, these vessels, which provide additional L-R shunts, effectively function as a miniature patent ductus arteriosus, placing the neonate at higher risk for heart failure, which developed in 11% of infants with systemic-to-pulmonary artery collaterals in one series.¹⁶⁸

Aberrant Congenital Systemic-to-Pulmonary Communications

In addition to persistent fetal systemic-to-pulmonary artery collaterals, other congenital vascular anomalies are recognized but rarely cause problems. The systemic artery is usually the internal mammary or a coronary artery. Iskandrian and colleagues¹⁶⁹ reported 12 patients with coronary-to-pulmonary artery communications, mostly discovered accidentally during routine coronary angiography for chest pain. Large-flow congenital systemic-to-pulmonary artery collaterals characteristically present in the second or third decade of life with a continuous murmur similar to that of a patent ductus arteriosus. Hearne and Burbank¹⁷⁰ reviewed 11 reported cases of communications between an internal mammary artery and the pulmonary arteries; 8 cases were considered to be congenital, 2 traumatic, and 1 neoplastic in origin.

Cavopulmonary Anastomoses

Systemic-to-pulmonary artery collaterals are a feature of Glenn/Fontan circulations constructed surgically as a palliative correction for tricuspid atresia or a functionally univentricular heart,¹⁷¹ operations that are also associated with the development of PAVMs in the lung deprived of hepatic venous blood (see Cavopulmonary Shunts earlier). In a retrospective series by McElhinney and associates,¹⁷²

59% of 76 patients had systemic-to-pulmonary artery collaterals on follow-up catheterization at approximately 2.5 years; their presence, however, was not associated with a poorer outcome.

TREATMENT

Treatment requirements depend on the presence of symptoms. Even systemic-to-pulmonary artery collaterals derived from coronary arteries generally do not “steal” blood flow from the coronary artery.¹⁶⁹ Whereas earlier cases from series spanning 1947 to 1979 were treated with ligation of the vessels and resection of the lobe, more recent cases were left untreated. Treatment is now offered in three settings: (1) for hemoptysis, the most common complication of acquired systemic-to-pulmonary artery collaterals, (2) for heart failure, predominantly affecting neonates with persistent fetal collaterals,¹⁷⁰ and (3) for high-flow-induced pulmonary hypertension in patients with Fontan circulations.¹⁷²

Managements of Hemoptysis

Hemoptysis from systemic-to-pulmonary artery collaterals may be massive and require emergency management. Bronchoscopy may help localize the source of bleeding,¹⁷³ but chest CT performed during the aortic phase of contrast enhancement is usually more informative; CT angiograms document the underlying cause of bleeding in most instances and clearly demonstrate the presence or absence of hypertrophied bronchial (see eFig. 19-3) or nonbronchial systemic arteries.¹⁷⁴ In an emergency, angiography takes precedence, with a view to proceeding quickly to embolization of the bleeding vessels. In 1977, Rémy and associates¹⁷⁵ reported their results of selective bronchial artery angiography and embolization in 105 patients with hemoptysis.

Bronchial artery or collateral vessel embolization is carried out at angiography with particulate polyvinyl alcohol; it is a highly specialized interventional radiology technique (see eFig. 18-19).^{176,177} Complications are uncommon, but one of the most feared is that of a transverse myelitis, which may result if a spinal artery arising from an intercostal or bronchial artery is inadvertently embolized. The use of “superselective” coaxial catheters (3-French gauge), with peripheral placement of the tip in a stable position distal to normal arterial branches and without reflux after injection, has made the procedure much safer.¹⁷⁶⁻¹⁷⁸ In 80% to 90% of cases, immediate control of hemoptysis is achieved,¹⁷⁹ although 20% rebleed in the first 6 months, and a further 50% have significant hemoptysis on longer follow-up; repeat embolization is usually helpful in these individuals. While bronchial artery embolization is not curative and the risk of further hemoptysis is always present, embolization can be repeated several times.

Surgery is falling out of favor as first-line treatment for massive hemoptysis for three main reasons: (1) the patient's condition is often poor, (2) the disease is usually extensive and often bilateral, and (3) pleural thickening is present and traversed by extensive collateral vessels that often adhere the lung to the chest wall. In 10 series, the average perioperative mortality for pleuropulmonary aspergilloma resection was 9% (range 0 to 23%).¹⁸⁰ Increasingly, surgery is

confined to low-risk cases in which recurrent hemoptysis is a problem.

PULMONARY SEQUESTRATION

CLASSIFICATION

Pulmonary sequestration, also called bronchopulmonary sequestration, was first described by Pryce¹⁸¹ in 1946 and defined by him as “an abnormal artery from the aorta supplying a bronchopulmonary mass or cyst which is dissociated from the normally connected bronchial tree.” A distinction is usually made between intralobar sequestrations, which share a common visceral pleural investment with the adjacent normal lung tissue, and the much less frequent extralobar sequestrations, which have their own pleural lining that separates them from the remaining lung tissue. Both types have an abnormal systemic blood supply, most often from the thoracic aorta but, in roughly 20% of cases, the artery originates from the abdominal aorta; atypical origins of the feeding vessels, even from coronary arteries, are well described. The venous drainage in intralobar sequestrations is generally via a pulmonary vein whereas, in the extralobar variety, it is often via the azygos vein, but variations are common.¹⁸²

PATHOGENESIS

During bronchial branching, which is completed in humans 16 weeks after conception, the dividing buds are supplied by a capillary plexus derived from the primitive aorta; this plexus later regresses. Growth arrest locally of the pulmonary artery during bronchial division may disrupt maturation and tracheobronchial integrity, as well as lead to persistence of the blood supply from the aorta. The developing lung bud lies in close proximity to the developing foregut, from which it is derived, which explains the high incidence of associated foregut anomalies and linkage with congenital cystic adenomatoid malformation. In 1987, Clements and Warner¹⁸³ developed an alternative nomenclature and anatomic classification that unifies these embryologically related anomalies, many of which are now being diagnosed in utero (eFig. 61-7) owing to the extensive use of prenatal imaging studies.¹⁸⁴

CLINICAL FEATURES

Most patients with sequestrations are symptomatic, and the diagnosis is made in 50% to 60% before the age of 20. Diagnosis in adults older than 50 is uncommon, but a series of 17 patients was recently reported.¹⁸⁵ According to a 1979 review of 540 cases by Savic and colleagues,¹⁸⁶ 15% of patients are asymptomatic.

Typically, symptoms develop during infancy or childhood and are characterized by chronic cough and recurrent pneumonias and episodes of acute bronchitis, which are related to underlying progressive bronchiectasis, scarring, and cyst formation in the poorly communicating sequestered lung. Hemoptysis is also common. Chest radiographs classically show a basal opacity, usually on the left (eFig. 61-8), but the right lung base may also be involved

(eFig. 61-9); less commonly, sequestrations may involve more superior intrapulmonary anatomic units. Intralobar sequestrations, when uninfected, often appear as lucent lesions (eFig. 61-10). In contrast, extralobar sequestrations are most commonly encountered in infancy, appear solid at chest imaging (eFig. 61-11), and rarely become infected.

The diagnosis depends on demonstrating the anomalous systemic arterial blood supply that can reliably be shown by multislice chest CT techniques (Fig. 61-7, see eFigs. 61-8B-D, 61-9G-J, 61-10, 61-11, and 61-12; Video 61-3; and eFig. 18-18). MR angiography is also a valuable means of diagnosing sequestration (see eFig. 61-9G-J), and has the advantage of not involving ionizing radiation,¹⁸⁷ but this may be offset by longer imaging times when compared with CT, particularly in pediatric patients, in whom sedation is required.¹⁸²

Figure 61-7 Pulmonary sequestration. The sequestration presented as a lung mass at the left lung base in an asymptomatic 55-year-old man (found on an employment radiograph). **A**, Coronal reformation from contrast-enhanced chest CT demonstrates the systemic arterial blood supply, which arises from the lower thoracic aorta (arrow) and supplies a soft tissue mass in the left lower lobe. **B**, Axial image on a lung window demonstrates the soft tissue mass with hyperinflation of the surrounding lung (arrowheads) due to disruption of the normal airway to this segment, resulting in air trapping.

TREATMENT

The recommended treatment of patients with symptomatic sequestrations is surgical removal of the affected lung, which often requires a lobectomy but which can sometimes be carried out by segmentectomy to conserve the normal portion of lung in patients with intralobar sequestrations. Recently, the feasibility of using video-assisted thoracic surgery has been demonstrated, but its final role in treatment is unknown.¹⁸⁸ A prerequisite of operative intervention is thorough definition of the origin and course of the aberrant arterial blood supply; Lee and coworkers¹⁸² believe also that an additional surgical advantage lies in the demonstration of the venous drainage pathways by chest CT examination. In patients in whom resection cannot be performed for technical reasons, ligation or embolization of the feeder artery is advised to prevent hemoptysis; embolization may also be performed preoperatively to help reduce blood loss.

PULMONARY VARICES

Pulmonary varices are uncommon and are generally only of importance in that they mimic other, more serious, pulmonary vascular anomalies. They are divided into congenital and acquired forms and are usually easily diagnosed on contrast-enhanced CT.

DIAGNOSIS AND TREATMENT

A *congenital pulmonary varix* represents a collateral intrapulmonary vein bypassing an atretic segment of normal pulmonary vein.^{58,189} This atretic segment is most commonly of a segmental or subsegmental vein, most commonly in the upper lobes, and the resultant intrapulmonary collateral vessel then courses through the lung, sometimes across a fissure, into the ipsilateral superior or inferior pulmonary vein (eFig. 61-13). This is not associated with pulmonary arterial hypertension and is not at risk for rupture.

Acquired pulmonary varices are described in association with long-standing severe mitral valve disease with associated pulmonary venous hypertension. Typically right-sided—thought to be due to the jet of regurgitant blood being directed towards this side—they have been reported as being at risk, not only for rupture with life-threatening hemorrhage but also for in situ thrombosis and resultant systemic thromboembolism. It has been suggested that there is a congenital weakness in the affected pulmonary vein wall, which allows the development of varices in response to pulmonary venous hypertension in these individuals, to explain the fact that they are rare whilst mitral valve disease is relatively common.

A second type of acquired pulmonary varix is seen in some patients in whom previous pulmonary tuberculosis or sarcoidosis has caused stenosis or occlusions of intrapulmonary venous branches and collateral veins have subsequently developed in order to bypass these areas. These collaterals typically cross fissures and are generally shorter and less well developed than the congenital form.⁵⁸ They do not appear to be associated with a risk for rupture and hemorrhage.

PULMONARY ARTERY ANEURYSMS

Pulmonary artery aneurysms (PAAs) are rare vascular anomalies. Historically they were classified as peripheral (predominantly tuberculous) or proximal (predominantly syphilitic). It is now recognized that PAAs can develop in a wide range of clinical settings and that the distinction between large and medium to small vessels is by no means absolute. Proximal PAAs tend to develop primarily due to inherited defects in the vascular wall, may be idiopathic⁵⁸ (eFig. 61-14) or result from trauma due to pulmonary hypertension or jets of blood impacting specific sites, such as immediately beyond a pulmonary valve stenosis (eFig. 61-15) or opposite a patent ductus arteriosus. They can also result from focal endovascular infection or vasculitis, or disease of the vasovasorum as in syphilis. Peripheral PAAs are more usually attributed to infection—either adjacent to an area of infected lung (as in tuberculous Rasmussen aneurysms) or due to endovascular seeding of infected foci—or to vasculitis. In many cases, more than one etiologic factor is present, and it is not clear whether an intrinsic vascular defect, endovascular trauma, or infection is primarily responsible for the development of the aneurysm. Multiple aneurysms should raise the possibility of underlying Behçet disease.

Pulmonary artery aneurysms are unstable structures: As the radius of the aneurysm increases, the wall tension becomes higher at any given level of intravascular pressure, thus increasing the dilating force via the Laplace relationship. Although only some aneurysms continuously dilate via this vicious circle until they rupture, all have the potential to do so. The main risks of these unstable structures are pulmonary hemorrhage—which may be life-threatening when they arise from any site—and dissection in the case of proximal lesions. In dissecting aneurysms, blood tracks through an intimal tear within the arterial wall. In false aneurysms (pseudoaneurysms), the blood breaches all the layers of the wall but is contained by the surrounding tissues or by clotting. If an aneurysm ruptures and is not contained in this way, blood may enter the bronchus sharing the common bronchovascular connective tissue sheath, causing hemoptysis and sometimes death from exsanguination.

ETIOLOGY AND PATHOGENESIS

In many cases, more than one etiologic factor is present. It is often not clear whether an intrinsic vascular defect, endovascular trauma, or infection is primarily responsible for the development of the aneurysm.

Infection

Small artery pseudoaneurysms are generally infective (mycotic) in origin, often mycobacterial or fungal. Pathologically, granulation tissue replaces a large part of the arterial wall. Tuberculosis and syphilis used to be the most common causes. Tuberculous Rasmussen aneurysms, classically described as the tortuous abnormal vasculature of tuberculous cavity walls, were seen in 4% of autopsies (45 of 1114) in patients with chronic pulmonary tuberculosis, and caused death in the majority of those patients in whom

they were present.¹⁹⁰ Rasmussen aneurysms remain important; in 1984, they were reported in approximately 5% of cases of massive hemoptysis.¹⁹¹ In contrast, in the current era of near universal treatment of syphilis, only 8 cases of untreated proximal syphilitic PAA were found in 109,571 autopsies.¹⁹²

Although the contribution of syphilis in particular has waned, infection remains a relatively common etiology, particularly secondary to tuberculosis or lung abscess. Other in situ pulmonary arterial wall infections result from endovascular seeding from right-sided heart valve vegetations, typically in chronic drug abusers,¹⁹³ or in one case, from *Candida* endocarditis introduced by a Swan-Ganz catheter.¹⁹⁴

Vascular Trauma

Large artery aneurysms have a variety of causes, the most common of which is congenital heart disease, especially patent ductus arteriosus; less common causes are pulmonary valve stenosis, atrial or ventricular septal defect, and Fallot tetralogy. The mechanism is thought to be trauma to the artery wall from jets of blood ejected at high velocity. External sources of trauma include penetrating injuries such as stab wounds¹⁹⁵ and tube thoracostomy.¹⁹⁶ Disruption of the arterial wall during inflation of pulmonary artery balloon catheters has led to a significant number of false aneurysms, particularly in patients with preexisting pulmonary hypertension or on anticoagulants, although this remains a rare complication.¹⁹⁷ Catheterization can cause a pseudoaneurysm if the vessel wall is lacerated by the catheter tip and bleeding is contained, temporarily or permanently, by the surrounding tissues (eFig. 61-16). Alternatively, a true aneurysm, with or without rupture, can develop if the catheter balloon is overinflated in a small branch of the pulmonary artery. Kearney and Shabot,¹⁹⁸ in a retrospective review of 32,442 patients requiring catheterization from 1975 to 1991, found that pulmonary artery rupture due to catheter balloon overinflation was associated with hemoptysis in 10 patients (0.03% incidence). The risk factors were both technical, related to peripheral placement and overinflation of the balloon, and pathophysiologic, the most important of which was age older than 60 years, which reflects the greater fragility of pulmonary arteries in older adults.

Weakness of the Arterial Wall

Vascular wall weakness may predispose to aneurysm formation. Large artery aneurysms have been reported in patients with giant cell arteritis,¹⁹⁹ and multiple aneurysms in Behçet syndrome (see eFig. 67-2) or the Hughes-Stovin syndrome.²⁰⁰ Pulmonary hypertension, when associated with atheromatous disease and cystic necrosis of the media, may lead to dissecting pulmonary artery aneurysms. Similarly, cystic necrosis and dissecting aneurysms are also caused by fibrillin deficiency in Marfan syndrome.²⁰¹

DIAGNOSIS AND TREATMENT

Pulmonary artery aneurysms usually come to light during the investigation of an unusual mass on a routine chest radiograph or during the workup for hemoptysis. Echocardiography (including transesophageal echocardiography),

CT scanning, and MR imaging are replacing angiography as first-line diagnostic investigations.²⁰² In the absence of hemoptysis, treatment should first be directed to the underlying cause (e.g., infection, vasculitis, pulmonary hypertension, and congenital heart disease). Such measures may not be possible in patients with hemoptysis in whom emergency treatment of the aneurysm is required. When the aneurysm does not include the pulmonary trunk or main pulmonary arteries, embolization is the treatment of choice using metal coils or detachable silicone balloons. Embolization is also becoming the preferred choice for large artery aneurysms.¹⁹⁹ When a pulmonary artery pseudoaneurysm is demonstrated, usually during selective bronchial arteriography that demonstrates a systemic artery-to-pulmonary artery shunt and pulmonary artery opacification, both bronchial and pulmonary artery embolization are likely to be necessary to control bleeding.²⁰³

Proximal aneurysms have been repaired by a variety of surgical techniques, including pulmonary artery banding or excision of the aneurysm and prosthetic patch replacement.²⁰⁴ Stents and grafts inserted endovascularly are likely to replace open heart surgery in some instances.²⁰⁵ Surgical resections in this group have been superseded because they result in excessive loss of parenchymal tissue and carry a high morbidity and mortality. Lung transplantation may be an option in patients with Group 1 idiopathic (primary) pulmonary arterial hypertension.²⁰⁶

Key Points

- Most pulmonary arteriovenous malformations are found in individuals with hereditary hemorrhagic telangiectasia, which is inherited as an autosomal dominant trait.
- Right-to-left shunting of blood through pulmonary arteriovenous malformations leads to hypoxemia, and paradoxical emboli that can present as cerebral abscess or ischemic stroke.
- Diagnosis is facilitated by CT techniques and contrast echocardiography.
- Embolization of pulmonary arteriovenous malformations with vascular plugs or coils decreases right-to-left shunting and the risk of paradoxical embolization. Small vessel malformations are difficult to close.
- Systemic to pulmonary communications are apt to be asymptomatic but may cause heart failure in neonates and hemoptysis in later life.
- Pulmonary sequestrations are supplied by an abnormal systemic artery, usually from the aorta, and lack a normal communication with the tracheobronchial tree. Symptoms, if they develop, may start at a young age and are characterized by cough and recurrent infections. Treatment is surgical removal.
- Pulmonary artery aneurysms are rare vascular abnormalities of varying etiology, whose major complication is hemoptysis. Diagnosis is usually made by CT and MR imaging. Treatment is directed at the underlying cause (infection, vasculitis, pulmonary hypertension, or congenital heart disease); hemoptysis is best treated by embolization.

eFIGURE IMAGE GALLERY

The figures and videos in the imaging gallery are not those of the chapter authors but have been separately chosen by the Editor of Thoracic Imaging in this and other chapters as additional examples of the pathology discussed.

Figure 61-1 Simple arteriovenous malformation (AVM): chest radiographic and chest CT appearance. Frontal (A) and lateral (B) chest radiographs show a lobulated peripheral solitary pulmonary nodule (arrows), associated with a faint tubular opacity (arrowhead), which leads directly to the nodule. C, Axial chest CT displayed in lung windows shows that the peripheral solitary pulmonary nodule (arrow) is clearly associated with enlarged vessels (arrowheads); this morphology is diagnostic of AVM. On this single image, it is not possible to distinguish the feeding artery and draining vein, but following these vessels on more cranially located images allows the arterial supply and venous effluent to be distinguished. (Courtesy Michael Gotway, MD.)

Figure 61-2 Complex arteriovenous malformation (AVM): chest radiographic and chest CT appearance. Frontal (A) and lateral (B) chest radiographs show several tubular-shaped left perihilar opacities (arrows) representing a combination of enlarged feeding arteries and draining veins. C-F, Axial chest CT displayed in lung windows shows an enlarged draining vein (single arrowhead, C) and two enlarged feeding arteries (arrows, D and F), supplying the AVM nidus (seen at the tip of the feeding artery in F). Lingular ground-glass opacities and small serpiginous structures (seen in F and double arrowhead, E, respectively) are consistent with increased pulmonary blood flow and small AVMs in this region. Several other feeding arteries were identified more inferiorly in the lingula as well. (Courtesy Michael Gotway, MD; case by Paul J. Conomos, MD, Arizona Pulmonary Specialists, Phoenix, AZ.)

Figure 61-3 Relatively small arteriovenous malformation (AVM): chest radiography and chest CT appearance. Frontal (A) and lateral (B) chest radiographs show a circumscribed, peripheral, small right lower lobe pulmonary nodule (arrows). Note the serpiginous structure (arrowheads) closely associated with the nodule; this morphology is suggestive of AVM. C, Axial chest CT displayed in lung windows shows that the circumscribed peripheral right lower lobe nodule (arrow) is associated with a vessel (arrowhead) entering the nodule; this morphology is characteristic of AVM. (Courtesy Michael Gotway, MD.)

Figure 61-4 Percutaneous transcatheter embolization treatment for arteriovenous malformation (AVM). Pretreatment frontal (A) and lateral (B) chest radiographs show a circumscribed left base mass (arrow) representing an AVM; an enlarged tubular structure (arrowhead), representing a feeding vessel, is faintly seen. C and D, Axial enhanced chest CT shows the intensely enhancing AVM nidus as well as the feeding artery (arrowheads) and draining vein (arrow). E, Catheter pulmonary angiography shows selective catheterization of the feeding artery (arrowhead) and opacification of the vascular nidus (arrow); the draining vein (double arrowheads) is also visible. F, Catheter pulmonary angiography following embolotherapy shows placement of a metallic coil (arrowhead) in the feeding artery. G and H, Axial enhanced chest CT displayed in lung windows following percutaneous transcatheter embolization treatment for AVM shows the coil in the feeding artery (arrowheads). The majority of the AVM nidus now shows no enhancement (compare with C and D), although some residual enhancement in a portion of the nidus (arrow, H) is visible; this residual shunt was due to very small, untreated feeding arteries. (Courtesy Michael Gotway, MD.)

eFigure 61-5 Percutaneous transcatheter embolization treatment for arteriovenous malformation (AVM). **A** and **B**, Pretreatment catheter pulmonary angiography shows a peripheral right pulmonary AVM (arrows). **C** and **D**, Following treatment, a coil (arrowheads) is present within the pulmonary artery feeding the vascular nidus, and flow is no longer identifiable within the nidus of the AVM. (Courtesy Michael Gotway, MD.)

eFigure 61-6 Systemic-to-pulmonary vascular communication. Frontal (**A**) and lateral (**B**) chest radiographs show faint increased attenuation and prominent vessels in the medial right inferior lung (arrows). **C-F**, Axial chest CT scans displayed in soft tissue windows show prominent vessels within an area of consolidation in the inferior right middle lobe (arrowheads); these vessels derived from the intercostal and internal mammary arteries. More superiorly, the tangle of vessels within the right middle lobe consolidation can be traced to a point where they enter the lung and anastomose with a peripheral pulmonary artery (arrow, **F**) (see [Video 61-2](#) for the full study). (Courtesy Michael Gotway, MD.)

eFigure 61-7 In utero diagnosis of extralobar sequestration. Sagittal MRI shows a large, aberrant artery (*arrow*) arising from the descending thoracic aorta (*arrowheads*). This vessel supplied a solid mass identified at prenatal sonography, proven on resection performed following birth to represent extralobar sequestration. The fetus is in a “head-down” position. A, maternal anterior; B, fetal brain; P, maternal posterior. (Courtesy Michael Gotway, MD.)

eFigure 61-8 Left lower lobe intralobar sequestration: chest radiographic and chest CT appearance. A, Frontal chest radiograph in a young adult with a history of recurrent left lung pneumonias shows homogeneous masslike medial left base opacity (*arrows*). B–D, Axial enhanced chest CT displayed in soft tissue windows shows a medial left base soft tissue mass in contact with the pleura; an enlarged vein (*arrowheads*) draining to the systemic venous circulation is present. Azygos vein (*arrow*, B) is present. The systemic arterial supply arising from the descending thoracic aorta (*double arrowheads*) is visible. (Courtesy Michael Gotway, MD; case by W. Richard Webb, MD, Department of Radiology, University of California, San Francisco.)

eFigure 61-9 Intralobar sequestration: right-sided location. Frontal (A) and lateral (B) chest radiographs show posteromedial right basal consolidation (arrows) with faint lucency (arrowhead). C-F, Axial chest CT displayed in lung windows shows posteromedial right base cystic change (arrowheads) and consolidation (arrows), typical of intralobar sequestration. This unenhanced chest CT did not adequately display the aberrant arterial supply to the sequestration. Axial unenhanced double inversion recovery (G-I) and oblique maximum intensity projected MR angiography (J) shows the posteromedial right basal consolidation as hyperintense, likely representing a combination of inspissated material and hemorrhage. The aberrant arterial supply is faintly seen as a hypointense linear structure (arrowheads) on the double inversion recovery images (G-I), but is well seen on the oblique coronal MR angiography images (arrows, J). The lesion was subsequently resected without complication. A, distal thoracic aorta. (Courtesy Michael Gotway, MD.)

eFigure 61-10 Intralobar sequestration: lucent appearance. A and B, Axial chest CT displayed in lung windows shows a focal area of lucency in the posteromedial right lower lobe supplied by a large, anomalous artery (arrows) arising from the descending thoracic aorta; the appearance is typical of an uninfected intralobar sequestration. (Courtesy Michael Gotway, MD.)

eFigure 61-11 Left lower lobe extralobar sequestration: chest radiographic and chest CT appearance. **A**, Frontal chest radiograph in a neonate shows a left base mass (*arrow*) associated with contralateral shift of the heart and mediastinum. **B** and **C**, Axial enhanced chest CT confirms a solid mass at the left base (*arrows*) and reveals an anomalous artery (*arrowheads*) arising from the descending thoracic aorta supplying the lesion, establishing the diagnosis of extralobar sequestration. (Courtesy Michael Gotway, MD.)

eFigure 61-12 Intralobar sequestration: anomalous systemic arterial supply. **A-D**, Axial enhanced chest CT displayed in soft tissue windows shows a posteromedial left lower lobe solid mass (*arrows*) supplied by an anomalous artery (*arrowheads*) arising from the descending thoracic aorta; the appearance is typical of sequestration, usually intralobar when encountered in an adult patient (see [Video 61-2](#) for the full study). (Courtesy Michael Gotway, MD.)

eFigure 61-13 Congenital pulmonary varices: chest radiographic, chest CT, and angiographic appearance. **A**, Frontal chest radiograph shows prominent tubular structures (*arrows*) that could represent the vasculature supplying an arteriovenous malformation (AVM); note resemblance to eFig. 61-2A. **B-J**, Axial chest CT displayed in lung windows shows bilateral serpiginous structures (*arrowheads*) consistent with enlarged vessels. In this circumstance, no vascular nidus, typical of an AVM, can be identified, and the enlarged vessels showed no arterial connection; they were all traceable to the left atrium. Catheter pulmonary angiography left pulmonary artery injection (**K-M**) and right pulmonary artery injection (**N-P**) show normal pulmonary arteries (*arrows*) during the early arterial phase of the injection; no enlarged artery supplying a vascular nidus could be identified. The venous phase of the injection (**L, M, O, and P**) shows opacification of the left atrium (LA) and subsequent opacification of the pulmonary varices (*arrowheads*) leading to the left atrium. A, aortic arch. (Courtesy Michael Gotway, MD.)

Figure 61-14 Main pulmonary artery aneurysm: chest radiographic and chest CT findings. Frontal (A) and lateral (B) chest radiographs show enlargement of the main pulmonary artery (arrows). C-E, Axial enhanced chest CT confirms enlargement of the main pulmonary artery (MPA), consistent with an aneurysm, with normal caliber right (R) and left (L) pulmonary arteries. The main pulmonary artery aneurysm was idiopathic; no specific etiology could be identified despite a thorough investigation. (Courtesy Michael Gotway, MD.)

Figure 61-15 Left pulmonary artery aneurysm due to valvular pulmonic stenosis: chest radiographic and chest CT findings. Frontal (A) and lateral (B) chest radiographs show enlargement of the left pulmonary artery (arrows). C, Axial enhanced chest CT confirms enlargement of the left (L) pulmonary artery, consistent with an aneurysm, with normal caliber right (R) pulmonary artery. MPA, main pulmonary artery. (Courtesy Michael Gotway, MD.)

eFigure 61-16 Traumatic left pulmonary artery aneurysm: chest radiographic and chest CT findings. Frontal (A) and lateral (B) chest radiographs show a large, round left perihilar structure (*arrows*). Cardiomegaly is present, and the patient had known congenital heart disease that required a recent intensive care unit stay, during which a pulmonary arterial catheter was placed. C, Axial enhanced chest CT shows a large lesion enhancing similar to other vascular structures, representing an aneurysm of the left pulmonary artery; note low attenuation peripheral thrombus. Review of the chest radiographs obtained while the patient was in the intensive care unit showed the tip of the catheter in the left pulmonary artery approximately in this location. (Courtesy Michael Gotway, MD.)

OUTCOME

Resolution of Pulmonary Edema
Overview

INTRODUCTION

Pulmonary edema—defined as excessive extravascular water in the lungs—is a common and serious clinical problem. Pulmonary edema can be life-threatening, but effective therapy is available to rescue patients from the deleterious consequences of disturbed lung fluid balance, which usually can be identified and, in many instances, corrected. Because rational and effective therapy depends on understanding basic principles of normal and abnormal liquid, solute, and protein transport in the lungs, this chapter begins with a brief overview of the major factors that govern fluid and protein filtration in healthy lungs before focusing on the pathophysiology of pulmonary edema. Next, the chapter discusses diagnosis, treatment, and resolution of pulmonary edema. Chapters 6 and 9 also provide additional information about the regulation of fluid balance in the lungs, and Chapter 100 includes details about the onset and management of acute lung injury and acute respiratory distress syndrome, as currently defined and subsequently discussed.

PATHOPHYSIOLOGY OF PULMONARY EDEMA

Pulmonary edema results when fluid is filtered into the lungs faster than it can be removed from them. Accumulation of fluid has serious consequences on lung function because gas exchange is greatly impaired in fluid-filled alveoli. Lung structure relevant to the forces governing fluid and protein movement in healthy lungs and lungs with pulmonary edema has been the subject of classic and more recent reviews.¹⁻⁶

There is always a net outward flux of fluid and protein crossing from the vascular space into the interstitium in the lungs, first, because the prevailing driving forces normally cause filtration out of the bloodstream and, second, because the microvascular endothelium is a permeable barrier that varies in its leakiness. Lung lymph flow, which represents the flow of fluid leaking across the microvascular barrier, normally is less than 0.01% of total lung blood flow. The

term *microvascular bed* (or *barrier*), is used throughout this chapter to refer to sites of fluid exchange. In addition to the vast interconnecting network of capillaries embedded in the alveolar walls, fluid is exchanged across capillaries in the interstitium at alveolar wall junctions (*corner vessels*) and across small interstitial arteries and veins.

The essential factors that govern fluid exchange in the lungs are expressed in the Starling equation for the microvascular barrier:

$$J_v = L_p S [(P_c - P_i) - \sigma_d (\pi_c - \pi_i)]$$

where J_v is the net fluid-filtration rate (volume flow) across the microvascular barrier; L_p is the hydraulic conductivity (“permeability”) of the microvascular barrier to fluid filtration (a measure of how easy it is for water to cross the barrier); S is the surface area of the barrier; P_c is the pulmonary capillary (microvascular) hydrostatic pressure; P_i is the interstitial (“perimicrovascular”) hydrostatic pressure; π_c is the capillary (microvascular) plasma colloid osmotic (or oncotic) pressure; π_i is the interstitial (perimicrovascular) fluid osmotic pressure; and σ_d is the average osmotic reflection coefficient of the barrier (a measure of how effective the barrier is in hindering the passage of solutes from one side of the barrier to the other).

The microvascular hydrostatic pressure is the principal force that causes fluid filtration in the lungs. If blood was not flowing through the lungs, the opposing hydrostatic and osmotic forces on either side of the microvascular barrier would be equal, their sum would be zero, and there would be no filtration. The pumping action of the heart causes blood to flow through the lungs and generates the microvascular hydrostatic pressure that establishes the steady-state values of the other driving pressures that cause filtration of fluid.^{5,7}

According to the Starling equation, the difference between the prevailing transmural hydrostatic pressures ($P_c - P_i$) and the colloid osmotic pressures ($\pi_c - \pi_i$) provides the “driving force” for fluid filtration. The actual amount of filtrate that forms at any given driving force is determined by the integrity of the barrier to filtration, which is reflected in the conductivity (L_p) and reflection (σ_d) coefficients. The equation predicts the development of two fundamentally different kinds of pulmonary edema: (1) *increased pressure*

Table 62-1 Safety Factors That Protect the Lungs Against Interstitial and Alveolar Edema Accumulation

1. Lung lymphatic system
2. Resorption into blood vessels
3. Drainage into the mediastinum
4. Drainage into the pleural space
5. Extremely low alveolar epithelial barrier permeability
6. Low alveolar surface tension (surfactant)
7. Active transport by alveolar and distal airway epithelial cells

pulmonary edema—when the net result of the driving forces increases, fluid filtration is forced across the barrier at a rate that exceeds removal by lymphatic drainage, and (2) *increased permeability pulmonary edema*—when the normal barriers to fluid filtration are damaged, typically by some form of injury, conductance of liquid and protein in the lungs is allowed to increase. A third type of pulmonary edema is caused by impaired lymphatic drainage of filtered fluid, but this has less clinical relevance than the other two types. The lymphatic drainage of the lungs provides a vital means for removing filtered fluid and proteins from the perimicrovascular interstitial space, as discussed later.^{5,7}

Because the healthy microvascular barrier is permeable, the alveolar barrier must serve as the principal protection against the accumulation of pulmonary edema. Fluid and protein do not normally move into alveoli because the alveolar epithelial barrier has a low permeability even to small molecules (similar to cell membrane permeability); in addition, any fluid that is filtered is continuously being pumped back into the interstitium by alveolar epithelial cells,² drained away from the alveolar walls through the interstitium, and removed by lymphatic vessels and the lung microcirculation.

The several factors (Table 62-1) that normally protect the lungs against edema have been called *safety factors*. Under normal conditions, the lymphatic system pumps filtered fluid and protein out of the lungs as rapidly as they are formed, even when filtration of fluid and protein from the bloodstream into the interstitium is increased. Increases in fluid and protein filtration across the microvascular barrier also can be drained away from the alveolar walls down the prevailing pressure gradient into the loose peribronchovascular connective tissue or can be resorbed directly into blood vessels.⁴ The lung lymphatics can increase their pumping capacity manifold, particularly when the microvascular wall has been injured.⁵

When the usual driving forces are upset by higher hydrostatic pressure, the increase in filtration of water across the microvascular barrier is much larger than that in protein flux because the microvascular barrier has a low protein conductance. This results in dilution (“wash-down”) of interstitial protein concentration and, thereby, an increase in the balance of the protein osmotic pressure opposing the higher hydrostatic pressure (because plasma protein concentration remains high). Furthermore, the interstitial gel also becomes hydrated and the exclusion volume for protein decreases, either because of swelling or because its composition changes as hyaluronan is washed out from the interstitium, reducing the concentration of protein by expanding the available volume.

Figure 62-1 Frontal chest radiograph in a 55-year-old man with increased pressure edema due to heart failure. The heart is enlarged and bilateral perihilar linear and ground-glass opacity are present. This distribution is often referred to as a “butterfly” pattern and is commonly seen with chronic volume overload. (Courtesy Michael Gotway, MD.)

The protein osmotic pressure safety factors work only when the microvascular barrier is normal—as in increased pressure edema. In contrast, if the endothelial barrier is injured and its functional integrity is compromised—as in increased permeability edema—barrier conductance increases and the osmotic reflection coefficient decreases, making this safety factor much less effective or even completely ineffective. The compliance of the interstitial space also protects the lungs against edema. Increases in interstitial volume result in only small elevations of interstitial pressure until the interstitial volume is large. This maintains the hydrostatic driving pressure across the alveolar barrier suitably low. When interstitial pressure within the lungs rises to greater than pleural pressure, fluid flows across the visceral pleura into the pleural space, where its effects on lung function are relatively minor. Pleural fluid is drained by lymphatics in the parietal pleural and, even when pleural liquid accumulates, does not flow back from the pleural space into the lungs. Fluid that does accumulate in the alveoli is pumped out by active ion transport.² There are several mechanisms that can up-regulate the rate of alveolar fluid clearance (see Chapter 9).

In summary, pulmonary edema results from increases in either driving pressures (increased pressure edema) or barrier conductance (increased permeability edema) or both combined. What distinguishes between the two types is barrier permeability, which is normal in increased pressure edema but leaky in increased permeability edema. Fluid flow into the lungs is driven across the barrier in both types of edema according to the prevailing pressures.

INCREASED PRESSURE EDEMA

Increased pressure pulmonary edema (Fig. 62-1) is caused by an increase in the net sum of driving forces for fluid filtration into the lungs. The essential feature of this edema is

that the barriers to fluid and protein flow into the lungs are functionally intact. Increased pressure edema is often called *cardiogenic, high-pressure, or hydrostatic pulmonary edema*.

Pathophysiology

The flow of fluid and protein into the lungs increases when the sum of driving pressures is elevated. If the rate of fluid accumulation exceeds the rate at which it can be removed, increased pressure edema results. Because the barriers limiting fluid and protein flow into the lungs are intact, the lungs are protected against edema by the prevailing (normal) safety factors. Especially important is the ability to protect against increases in the principal driving pressure, lung microvascular hydrostatic pressure. Because of the low protein conductance of the microvascular barrier, fluid flow increases much more than protein flow when microvascular hydrostatic pressure rises. Interstitial protein concentration is diluted both by this higher fluid flow relative to protein flow and by a diminished exclusion volume for proteins as the interstitial gel is hydrated and swells. Lower interstitial protein concentration, owing to washout of interstitial proteins, results in lower perimicrovascular protein osmotic pressure and thereby a greater protein osmotic pressure difference across the barrier, which opposes any rise in hydrostatic pressure. In experimental animals, slightly less than 50% of an increase in hydrostatic pressure is offset by the increase in osmotic pressure difference.^{7,8} Increased pressure edema may be gradual in onset and progression because any elevation in microvascular hydrostatic pressure is attenuated by a rise in protein osmotic pressure difference across the microvascular barrier, owing to a decline in interstitial protein osmotic pressure.

The consequences of increased pressure edema on lung mechanics and gas exchange (Table 62-2) depend on how much edema accumulates.⁹ Deliberate dehydration of healthy subjects increases lung volumes and improves tests of ventilatory function.¹⁰ Early in the development of pulmonary edema, increases in hydrostatic pressure result in enlargement of the intrapulmonary blood volume, as

vessels, including capillaries, are both recruited and distended, which causes the *diffusing capacity of the lung* (DL_{CO}) to increase above normal; similarly, arterial *oxygen pressure* (PO_2) may rise because ventilated units are better perfused when vascular pressures increase.¹¹ The small reversible changes in airflow resistance and dynamic compliance, unaffected by vagotomy, in congested lungs appear to be due to reflex bronchoconstriction responses, but only when baseline bronchial tone is normal.¹²

When interstitial edema is present, closing volume may be increased and maximum expiratory airflows may be decreased. These changes were originally thought to be due to a decrease in caliber of small airways caused by compression by rising volume and pressure in the peribronchovascular connective tissue spaces. This effect would have to be in airways larger than bronchioles, because bronchioles and smaller airways do not have loose connective tissue sheaths¹ and their diameter is a function of lung volume, not transpulmonary pressure. Arterial PO_2 often falls as a result of ventilation-perfusion mismatching, but gas exchange is not seriously compromised until the alveoli are flooded.

With alveolar flooding, lung volumes are diminished.¹⁰ This is most marked in measurements of vital capacity, with inspiratory capacity affected more than expiratory capacity. Airways may close at higher than normal distending pressures, resulting in trapping of larger volumes of gas in the lungs.¹¹ Lung compliance is reduced when alveolar edema is present because lung volume decreases. Gas exchange becomes severely compromised when flooded alveoli remain perfused, causing *right-to-left shunts*,¹² and there is an increase in *wasted ventilation* (ventilation of units in which there is decreased or absent perfusion).

Light and electron microscopic examination of human and animal lung tissue in increased pressure edema shows alveolar edema and hemorrhage; thickened interstitial compartments (especially large peribronchovascular fluid cuffs) with separated, dispersed collagen fibrils; and increased capillary surface area and volume.¹³ More intercellular vesicles can be seen, but otherwise there are no detectable changes in the ultrastructure of the vascular endothelium, and the gap widths at intracellular junctions are not different from those in normal lungs. Long-standing pulmonary edema (e.g., in patients with chronic mitral stenosis) can be associated with basement membrane thickening and increased distance between the alveoli and the capillaries; increases in fibroblasts, histiocytes, and bulky strands of collagenous fibers can be seen in the interstitium. Dogs with pacing-induced chronic congestive heart failure developed a significant increase in the threshold for high-vascular-pressure edema formation—about a 50% reduction in the amount of water and protein cleared across the lung microvascular endothelial barrier at high pulmonary vascular pressures—compared with control animals. Morphometric analysis of the alveolar-capillary barrier showed that endothelial, interstitial, and epithelial thicknesses were all increased compared with controls, indicating that remodeling may confer an increase in the resistance to development of high-pressure-induced alveolar edema. Alveolar type II cells may be more numerous than in normal lungs, and alveolar macrophages proliferate.¹⁴ Sites of chronic severe increased pressure edema may also become

Mechanisms

By far the most common cause of increased pressure edema is elevated lung microvascular hydrostatic pressure. The influence of driving pressures would be greater than usual if either perimicrovascular hydrostatic pressure or protein osmotic pressure difference across the microvascular barrier was decreased. At the alveolar barrier, an increase in interstitial hydrostatic pressure, a decrease in alveolar hydrostatic pressure, or a decrease in osmotic pressure difference across the barrier could result in a greater sum of driving pressures. The possibilities are listed in Table 62-3.

Increased Microvascular Hydrostatic Pressure. Congestive heart failure is the most common cause of increased pressure edema. That is why increased pressure edema is often called “cardiogenic,” even though the heart is not always primarily involved. Elevated pressures in the pulmonary microvasculature are usually due to left-sided heart failure, with elevated left atrial pressures transmitted retrograde into the pulmonary circulation. Common causes are left ventricular dysfunction (e.g., caused by acute myocardial infarction, severe coronary insufficiency, tachyarrhythmias, bradyarrhythmias, cardiomyopathies, constrictive pericarditis, aortic stenosis or regurgitation, mitral regurgitation, coarctation of the aorta, rupture of chordae tendinae or intraventricular septum, systemic hypertension) or mechanical obstruction of the left atrial outflow tract (e.g., mitral stenosis, left atrial myxoma). Left atrial and pulmonary microvascular pressures can also be elevated by severe fluid volume overloading in a patient with a normal or diseased heart.

An unusual cause of increased microvascular hydrostatic pressure is pulmonary venous hypertension in the absence of left ventricular or atrial disease, which can arise if the pulmonary veins are contracted (e.g., by possible muscular sphincters), compressed, or obstructed (e.g., because of veno-occlusive disease or mediastinal fibrosis). Bronchial venous hypertension, in contrast, does not appear to significantly increase fluid filtration in the lungs.¹⁶

Increases in fluid filtration also can be associated with increases in vascular pressure proximal to the filtration sites in the lungs. For example, pulmonary hypertension, combined with depressed left ventricular function, has been implicated in the pathogenesis of cocaine-induced pulmo-

nary edema. Whether such increases lead to pulmonary edema depends on what happens to microvascular pressure. If high right-sided pressures are caused by increased resistance proximal to the main site of filtration in the lungs—as found in hypoxic pulmonary vasoconstriction of small arterial vessels,¹⁷ primary pulmonary hypertension, and pulmonary artery or valvular stenosis—pulmonary edema does not develop. Conversely, if the lung vascular bed is only partially constricted or obstructed, or if the vascular surface area is greatly decreased (e.g., by lung resection), higher flow in perfused vessels can lead to increased pressure edema,¹⁸ because microvascular pressures at the fluid exchange site are elevated in the overperfused lung. For example, pulmonary edema resulted in about 15% of patients after pneumonectomy and seemed to be exacerbated by administration of fresh frozen plasma,¹⁹ in part because intravascular volume is presumably increased by such transfusions. Any increase in blood flow through the lungs increases the pulmonary microvascular pressure at the fluid exchange sites even when pulmonary venous pressure remains constant.

The mechanism of an uncommon cause of pulmonary edema, *high-altitude pulmonary edema*,²⁰ which is also discussed in Chapter 77, may also be related, in part, to elevated pulmonary vascular pressures. As noted earlier, overperfusion of a restricted pulmonary vascular bed, even in the absence of hypoxia, causes increased pressure edema, not increased permeability edema.¹⁸ This can explain why some cases of high-altitude pulmonary edema are correctly classified as increased pressure pulmonary edema. Evidence from climbers studied at high altitude suggests that high intravascular pressures cause physical damage to vascular walls (so-called stress failure). In experimental animals, stress failure has been demonstrated after extreme, but sometimes transient, increases in pulmonary vascular pressures.²¹ Such structural failures need not happen in large numbers to explain an increase in permeability edema, because edema would form readily and in a quantity driven by the prevailing elevated vascular pressure.²² The suggestion has been made that high-altitude pulmonary edema results from the stress failure of overdistended, relatively thin-walled pulmonary arteries rather than from microvascular rupture,²³ which might help explain why the prevailing vasoconstriction does not seem to offer much protection to downstream vessels, why there are no reports of gradual progression through an indolent prodrome of increased pressure edema before stress failure results, and why high-altitude pulmonary edema is first detected radiographically in the central lung fields surrounding large vessels rather than in the lung bases and periphery.

Alternative mechanisms for the increased permeability in high-altitude pulmonary edema have been proposed. However, inflammatory responses in high-altitude pulmonary edema may be a consequence rather than a cause of the edema.²⁴ The rapid reversibility of high-altitude pulmonary edema with descent to lower elevation, oxygen therapy, or pharmacologic reduction of pulmonary vascular pressure is not characteristic of increased permeability pulmonary edema with coexisting inflammation.

*Neurogenic pulmonary edema*²⁵ also may be related in part to elevated pulmonary vascular pressures (Fig. 62-2). Measurements of edema fluid protein concentration relative to

plasma protein concentration in 12 patients with neurogenic pulmonary edema have been reported. Seven of the patients had ratios typical of increased pressure pulmonary edema, and the other five had ratios consistent either with increased permeability pulmonary edema or with late sampling during the resolution phase of increased pressure pulmonary edema, because edema fluid protein concentration

rises as fluid is reabsorbed from the alveoli at a faster rate than protein.

Decreased Perimicrovascular Hydrostatic Pressure.

The sum of driving pressures would increase if perimicrovascular hydrostatic pressure was greatly diminished, thereby resulting in an increase in fluid and protein filtration at the microvascular barrier in the lungs. Pulmonary edema has been described in circumstances in which this might happen. The best clinical example may be *postobstructive pulmonary edema* as a consequence of upper airway obstruction or its release, which can be caused, for example, by laryngospasm, endotracheal tube obstruction, foreign body aspiration, epiglottitis, croup, severe acute asthma, airway compression by tumors, strangulation, or hanging. High negative intrathoracic pressures generated by inspiratory attempts against the occluded airway are transmitted to the interstitium, promoting fluid movement into the interstitium. Mechanical effects on the cardiovascular system likely contribute to this kind of edema. High negative intrathoracic pressure causes increases in cardiac preload and afterload and in pulmonary blood flow, all of which increase the microvascular pressure that drives fluid out into the interstitium. In three patients with upper airway obstruction and pulmonary edema, all had low edema fluid protein concentration relative to plasma protein concentration (ratios of 0.44, 0.31, and 0.52), indicating increased pressure pulmonary edema.²⁶

Aspiration of air or fluid from the pleural space with consequent reexpansion of a collapsed lung could result in a decrease in perimicrovascular hydrostatic pressure as the lung expands to fill the thorax. So-called *reexpansion pulmonary edema* has been reported both in experimental animals²⁷ and in patients²⁸ after lung reexpansion (Fig. 62-3), but the high edema fluid protein concentration measured in three patients²⁹ indicated that reexpansion may result in an increased permeability edema rather than an increased

Figure 62-2 Frontal chest radiograph in a patient with subarachnoid hemorrhage and both increased intracranial pressure and neurogenic pulmonary edema. Multifocal bilateral consolidation and ground-glass opacity, somewhat upper lobe predominant, is present. The patient's volume status was normal and no clinical evidence of infection was present. pressure edema. However, another study of protein concentration in pulmonary edema fluid from patients with reexpansion edema indicates that hydrostatic mechanisms predominate.³⁰ The increased permeability hypothesis was supported in studies of rabbits with experimental reexpansion edema.³¹ Reperfusion injury is one of the causes of the pulmonary edema seen in transplanted lungs and appears to be predominantly an increased permeability edema.³²

If high alveolar surface tension was transmitted to the interstitium, perimicrovascular hydrostatic pressure would also be lowered, thereby increasing filtration across the microvascular barrier. Such an effect has been suggested by experimental findings in dog lungs.³³ The effect of alveolar surface tension on lung fluid balance is discussed later.

Decreased Transmural Protein Osmotic Pressure Difference. The sum of driving pressures would be increased if the protein osmotic pressure difference opposing the hydrostatic pressure difference across the microvascular barrier was decreased, either by lowering plasma protein concentration or by raising interstitial protein concentration, resulting in an increase in the sum of driving pressures for fluid and protein flow into the lungs. This theoretical mechanism of increased pressure edema has been the subject of study in experimental animals, with contradictory results.³⁴ When plasma protein osmotic pressure is low, the ability of the osmotic pressure gradient to widen in response to increased hydrostatic pressure is diminished, and edema accumulates at hydrostatic driving pressures lower than those needed to cause edema when protein concentration is normal.

Alveolar Barrier Function. If interstitial hydrostatic pressure was raised or if alveolar hydrostatic pressure or the osmotic pressure difference across the alveolar barrier was lowered, driving pressure for fluid and protein flow across the alveolar barrier would be elevated, resulting in increased pressure edema. Interstitial hydrostatic pressure rises as interstitial edema accumulates in the lungs.^{4,35} Increased interstitial hydrostatic pressure would raise the sum of driving pressures across the alveolar barrier and could drive edema formation across the alveolar or airway epithelium.

Greater pressure filtration across the alveolar barrier would also result from an increase in the sum of driving pressures if alveolar hydrostatic pressure was lowered. This is complicated by the interrelation between alveolar and interstitial hydrostatic pressures.^{4,36} A drop in alveolar hydrostatic pressure, which increases the sum of driving pressures across the alveolar barrier, also results in a lowering of interstitial hydrostatic pressure, which decreases the sum of driving pressures across the alveolar barrier but increases the sum of driving pressures across the microvascular barrier. Administration of a detergent aerosol resulted in loss of surfactant activity, higher alveolar surface tension, lower static compliance, atelectasis, and pulmonary edema; low protein concentration in alveolar edema fluid and left-hilar afferent lymph relative to plasma protein concentration indicated that this was an increased pressure type of pulmonary edema.³⁷ Because increased pressure edema can impair surface activity of dog lung extracts and isolated rabbit lungs, it is possible that changes in alveolar surface

tension may accelerate edema formation. However, the notion that changes in alveolar surface tension in edema lead to a self-perpetuating vicious circle of edema formation is not borne out clinically.

The only kind of clinical pulmonary edema caused by transmural osmotic pressure differences is near-drowning.³⁸ Seawater is three times more hyperosmotic (1000 mOsm) than plasma, so the volume of fluid in the air spaces after saltwater aspiration increases threefold to reach osmotic equilibrium, thus markedly increasing the alveolar edema already present owing to the volume of aspirated seawater itself in the alveoli. Osmotic equilibrium is reached in minutes as water is drawn from neighboring blood vessels into the alveoli by osmotic pressure.³⁹ Alveolar barrier function is not significantly compromised (unless perhaps the patient aspirates gastric contents or the seawater is contaminated or rich in particulate matter), and the alveolar edema is cleared rapidly (50% to 60% of excess alveolar fluid is cleared in 4 hours). Freshwater near-drowning proceeds in the opposite fashion: osmotic equilibrium is reached rapidly by flow of water out of the alveoli into the interstitium and bloodstream. Rapid water flux and hypotonicity can cause severe hemodilution, with hemolysis and fibrinolysis, as well as severe distortion of pulmonary ultrastructure, including damage to type I and type II cells, endothelial cell swelling, basement membrane detachment, and cell disruption. Both the alveolar epithelium and microvascular endothelium can thus be injured by the hypotonic fluid, leading to increased permeability pulmonary edema rather than a normal barrier type of pulmonary edema.

INCREASED PERMEABILITY EDEMA

Increased permeability pulmonary edema (Fig. 62-4) is caused by an increase in liquid and protein conductance across the barriers in the lungs. The essential feature of this edema is that the integrity of the barriers to fluid and protein flow into the lung interstitium and alveoli is altered from lung parenchymal damage. Increased permeability

Figure 62-4 Frontal chest radiograph in a patient with increased permeability edema. Bilateral consolidation, more prominent on the left, is present. The heart is not enlarged and no pleural effusions are present. No features typical of volume overload are evident. (Courtesy Michael Gotway, MD.)

edema is sometimes called *noncardiogenic pulmonary edema*, and the resulting clinical syndromes in humans—when explicitly defined (see later)—are referred to as *acute lung injury* (ALI) or, when severe, the *acute respiratory distress syndrome* (ARDS).⁴⁰

Pathophysiology

If the rate of fluid and protein accumulation from lung endothelial and epithelial barrier injury exceeds the rate at which it can be removed, increased permeability edema results. Because the barriers limiting fluid and protein flow into the lungs do not function normally when the lungs are injured, the lungs are not protected against edema by the usual safety factors. Although increases in fluid and protein filtration across the barriers are removed by lymphatics and drained away from the alveolar walls as in increased pressure edema, much more fluid and protein are filtered at any given sum of driving pressures because the barriers to their flow are much less restrictive than normal. Edema formation in injured lungs becomes extremely sensitive to driving pressures.²² Driving pressures are often increased when the lungs are injured because of the vasoconstrictive effects of inflammatory mediators such as thromboxanes, which may shift the main site of resistance to postcapillary venules, thus increasing hydrostatic pressure at the microvascular fluid exchange sites,⁶⁷ or because of effects on the heart as well as on the circulation. For example, elevated left atrial pressure, pulmonary venoconstriction, and an increase in cardiac output in sepsis can increase hydrostatic pressure at the microvascular fluid exchange sites.⁴¹

Because the endothelial-epithelial barrier becomes leaky, protective protein osmotic pressure differences are lost across them, driving pressure is unopposed by protein osmotic pressure, and even normal hydrostatic pressure results in significant fluid and protein extravasation into interstitial and alveolar spaces. The ability of the lymphatics to pump the excess filtrate away is increased when the lungs are injured. Maximal lung lymph flow increases more when the microvascular wall has been injured than when hydrostatic pressure alone is increased, but even this augmented lymphatic pumping capability is taxed at low driving pressures. If the epithelial barrier is injured, edema may accumulate readily in the alveoli, because most of the resistance to fluid and protein flow into the alveoli resides in the epithelial barrier.⁴² Increased permeability edema is often rapid in onset and progression because injured barriers offer much less resistance to flow and because hydrostatic driving pressure is unopposed by increases in osmotic pressure difference. Clinically, patients with increased permeability edema usually have a low intravascular hydrostatic pressure, commonly measured as a low or normal pulmonary capillary wedge pressure. In some cases, this reflects the low intravascular pressures associated with the underlying disease process (e.g., sepsis).

The consequences of increased permeability edema on lung mechanics and gas exchange depend on how much edema accumulates and how severe the causative lung injury is.⁴³ As with increased pressure edema, the major effects on pulmonary mechanics follow alveolar flooding. In experimental lung injury, functional residual capacity decreases as a consequence of alveolar flooding, and this loss of ventilated units accounted for virtually all the

observed decrease in static lung compliance.⁴⁴ *Computed tomography* (CT) has provided new insights into structure-function relationships in human ALI.⁴⁵ In its early stage, when alveolar edema predominates, the lungs are characterized by a homogeneous alteration of vascular permeability, and edema accumulates evenly in all lung regions with a nongravitational distribution. Increased lung weight due to edema causes collapse of lung regions along the vertical axis through the transmission of hydrostatic forces (compression atelectasis, caused by the weight of edema). Thus lung volume is lost mainly in the dependent lung, where the superimposed weight from above is greatest.

Measurements of pulmonary mechanics in mechanically ventilated patients with diffuse parenchymal lung damage showed decreased static lung compliance as a consequence of loss of ventilated lung. In addition, airflow resistance was increased as a result of decreased lung volume.⁴³ Bronchospasm may add to the increase in airflow resistance and can be substantially reversed by bronchodilator inhalation.⁴⁶ Chest wall compliance was reduced, probably because of alterations of intrinsic mechanical properties of the chest wall by abdominal distention, chest wall edema, and pleural effusion.⁴³ Different respiratory mechanical abnormalities and responses to *positive end-expiratory pressure* (PEEP) during mechanical ventilation were reported in patients with severe increased permeability edema originating from pulmonary disease (pneumonia with consolidation) or from extrapulmonary disease (associated with pulmonary edema and alveolar collapse).⁴⁷

Although the effects of surface forces on decreased lung compliance in patients with diffuse lung damage were thought to be small, results of experiments in isolated rabbit lungs indicated that increased permeability edema may result in more severe mechanical changes than equivalent degrees of increased pressure edema. Surfactant is thromboplastic, and coagulation may compound surfactant depletion when plasma proteins enter the air spaces. The injured lung may release substances that interfere with the normal low surface tension in the alveoli,⁴⁸ and activated *polymorphonuclear leukocytes* (PMNs) impair surfactant function in vitro and degrade the major surfactant apoproteins by proteolysis and oxidant-radical-mediated mechanisms.⁴⁹ Human lung surfactant obtained by *bronchoalveolar lavage* (BAL) of patients at risk for diffuse lung damage and patients with established injury is abnormal in chemical composition and functional activity.⁵⁰ Abnormalities also could be caused by interactions between surfactant and edema proteins, because plasma proteins (especially fibrin monomers but also fibrinogen and albumin) interfere with surfactant function. Proteinaceous edema fluid has been associated with surfactant inhibition in various experimental models.⁵¹ The role of surfactant in the development and treatment of diffuse parenchymal lung damage and the potential role for surfactant therapy are discussed in more detail later in this chapter.

Gas exchange is often severely compromised in increased permeability edema, owing both to intrapulmonary shunting of blood and to ventilation-perfusion inequalities.⁵² Patients with early lung injury typically have a marked increase in their pulmonary dead-space fraction, indicating that many ventilated lung units are not well perfused, although intrapulmonary shunting may also contribute to

the elevated dead space⁵³; this finding explains why minute ventilation rises to twice normal (12–16 L/min) at the onset of severe increased permeability edema. An elevated pulmonary dead-space fraction also has been reported in pediatric patients with widespread lung injury,⁵⁴ the mechanism for which may in part be explained by an increase in procoagulant and antifibrinolytic pathways in parenchymal damage.

The physiologic abnormalities associated with increased permeability edema are dominated by early alveolar flooding and depend on the severity and the duration of injury as well as its cause. Manifestations may resolve or worsen, but typically evolve in three pathologic patterns: exudative, proliferative, and fibrotic, usually in sequence. The earliest changes are marked by widespread alveolar and interstitial edema and hemorrhage. Injury to alveolar ducts may be particularly severe. Hyaline membranes, composed of precipitated plasma proteins, fibrin, and necrotic debris, can be seen. The alveolar epithelium may be more extensively damaged than the vascular endothelium, even if the underlying insult is blood-borne. Widespread, local areas of alveolar destruction, particular of type I alveolar epithelial cells, alternate with normal-appearing alveoli. The injured alveolar epithelium is swollen, disorganized, discontinuous, and often lifted off the exposed, but usually intact, basement membranes, which are covered by hyaline membranes. Type II cells are nearly always less severely damaged than type I cells, because their thin squamous cytoplasmic extensions, distant to the nucleus covering the thin side of the alveolar-capillary barrier, are frequently most gravely affected. The interstitium is widened by edema (especially in peribronchovascular cuffs) and may have leukocytes, platelets, red blood cells, fibrin, and debris (especially near the alveolar walls). The microvascular endothelium is often relatively preserved, usually showing little other than irregular focal thickening as a result of cytoplasmic swelling or vacuoles and greater numbers of luminal leukocytes, although frank swelling of endothelial cells may be seen on ultrastructural histology.

The exudative phase is followed by a proliferative phase, which begins within the 5 to 7 days after the onset of injury.⁵⁵ The relative contributions of the original insult, repair processes, and effects of therapies to this and subsequent phases are not well known, but some of the abnormalities after the initial exudative phase were related to the effects of traditional modes of mechanical ventilation that used tidal volumes between 12 and 15 mL/kg predicted body weight.⁵⁶ In the proliferative phase, some of the edema fluid has been reabsorbed from the air spaces. Fibrin may be prominent in alveoli and interstitium, and there is infiltration with inflammatory cells and fibroblasts. The alveolar epithelium is often cuboidal, made up largely of proliferating type II cells. The air-blood barrier can be thickened by interstitial and epithelial enlargement. The pulmonary vascular bed may be partially or completely disrupted, and structural alterations may reduce its surface area.

A final stage may follow, often about 10 to 14 days after the initial insult, in which fibrotic changes of the alveolar ducts, alveoli, and interstitium predominate: alveoli may be obliterated, alveolar walls coalesced, and functional lung units lost. Less commonly, the lungs show emphysema-like bullous changes.⁵⁵ Pulmonary function test results in

Mechanisms

The major types of clinical conditions that have been associated with increased permeability edema are listed in Table 62-4. The most common causes are pneumonia, sepsis, gastric aspiration, and major trauma. The lungs are injured via either the airways or the bloodstream. The exact mechanisms by which diffuse lung injury leads to increased permeability edema have been the subject of intense investigation in humans, animal models, and cellular systems.⁵⁶ Human studies have provided descriptive data about events in the air spaces before and after the onset of lung injury. Studies using BAL in patients before and after the onset of diffuse lung damage have shown that there is a major acute inflammatory response that begins before lung injury is clinically recognized, peaks during the first 1 to 3 days of clinical involvement, and then resolves slowly over the next 7 to 14 days in patients who remain intubated.^{57,59} These studies have shown the complexity of the evolving inflammatory responses, which are characterized by the accumulation of acute response cytokines and their inhibitors, oxidants, proteinases and antiproteinases, lipid mediators, growth factors, and collagen precursors involved in the repair process.^{57,60-66} Extensive efforts have been made to find single biologic markers that predict the onset or the outcome of diffuse parenchymal lung injury, but these have met with only limited success.^{67,68}

Hypotheses about mechanisms of lung injury have been tested in animal models and in vitro studies, and several reviews have summarized the findings.^{56,69} The existing animal models do not completely reproduce all of the various aspects of different injuries in humans, in part because human injuries typically evolve over a longer period of time than can be studied in the laboratory. In addition, the lungs of humans are exposed not only to the initial injurious insult but also to the therapies that are used for treatment, such as mechanical ventilation. Experiments with isolated cells have been useful to test specific concepts, but the complexity and redundancy of intact biologic systems are not reproduced in simplified experimental systems. Most experimental work purposely limits a study to a single causative agent; however, this turns the reality of clinical complexity into the simplicity of a single experimental pathway. Increased permeability edema in humans is likely to be caused by interactions between a number of different pathways acting in parallel or in series.

Studies in isolated organs and small animals in which hemodynamic variables are not measured can be difficult to evaluate because indices of lung injury, usually measured by the appearance of markers in lungs, lavage fluid, or perfusate, are not determined solely by the barrier function of the microvasculature. For example, when the vascular endothelium is injured, movement of fluid and protein from the vascular space into the lungs is extremely sensitive to hydrostatic driving pressures and surface area for filtration,²² and the effects of experimental interventions may be caused by changes in these parameters and not solely by changes in microvascular barrier function. The effects of microvascular driving pressures and surface area can be difficult to evaluate even in large, instrumented animals. Data from experimental animal models suggest that there are at least two broad categories of mechanisms of increased permeability edema: those that are *direct* (i.e., not requiring intermediary mechanisms, with injury a direct result of contact between an offending substance and lung tissue) and those that are *indirect* (i.e., requiring the participation of intermediary mechanisms, such as host defenses). These categories overlap because, once the lungs are injured, inflammatory responses may compound the primary mechanism of injury. Three major hypotheses about the mechanism of increased permeability pulmonary edema have been proposed, and are interrelated. A recent review provides specific information on animal models of experimental lung damage and an American Thoracic Society Consensus Conference provided further recommendations.⁶⁹

DIAGNOSIS

The diagnosis of moderately and, especially, severely advanced pulmonary edema, particularly when caused by heart failure, is usually fairly easy. Unraveling the cause of other kinds of pulmonary edema may not be so straightforward, particularly in patients with increased permeability edema.

CLINICAL ASSESSMENT

Definitions

Newcomers interested in the history of catastrophic lung disease should remember the clinical anecdotes that began to surface as far back as the 1950s, 1960s, and 1970s showing that little by little survival from what had been known as “shock lung,” “Danang lung,” and “adult respiratory distress syndrome” represented a gigantic medical-technical-operational breakthrough. Previously, virtually *all* such egregiously wounded or injured casualties died. (The name *adult* changed to *acute* respiratory distress syndrome, but the familiar acronym ARDS remained.) Subsequently, the number of survival miracles steadily increased, but mortality remained high.

Conceptually, ALI comprise a continuum of lung damage ranging from trivial to severe or lethal. For decades and by general agreement, the term “ARDS” has defined the most grievously afflicted victims of the syndrome. In 1988, an “expanded definition” with numerical grading of ARDS was proposed,⁷⁰ and 6 years later it was recognized that the

term ALI could be “applied to a wide spectrum of this continuum of pathologic process so as to acknowledge and define it”⁷¹; moreover, the term ARDS continued to represent the most severe end of the ALI spectrum of damage.

To satisfy clinical and epidemiologic needs, three different definitions of lung damage have been widely used, but each has its shortcomings: the Acute Lung Injury Score,⁷⁰ the *American-European Consensus Conference* (AECC) definition,⁷¹ and a recent revision of the AECC definition termed the “Berlin Definition of ARDS.”⁷²

The Lung Injury Score (Table 62-5) provides an assessment of the severity of lung injury, taking into account supportive therapy, such as mechanical ventilation with PEEP and oxygen supplementation.⁷⁰ This score is important because not all lung injuries are of equal severity and severity changes over time. In this scoring system, ARDS defines only the most severe injuries (those that yield a score >2.5); milder lung injuries, termed mild-to-moderate, may have a better prognosis and may differ from ARDS in other important aspects. This scoring system has been used widely in clinical research and clinical trials.

The American-European Consensus Conference Definition⁷¹ (Table 62-6) has four elements: (1) timing (onset

Table 62-5 Components and Individual Values of the Lung Injury Score

1. CHEST RADIOGRAPH SCORE	VALUE
No alveolar consolidation	0
Alveolar consolidation confined to 1 quadrant	1
Alveolar consolidation confined to 2 quadrants	2
Alveolar consolidation confined to 3 quadrants	3
Alveolar consolidation in all 4 quadrants	4
2. HYPOXEMIA SCORE	
PaO ₂ /Fio ₂ ≥ 300	0
PaO ₂ /Fio ₂ 225–299	1
PaO ₂ /Fio ₂ 175–224	2
PaO ₂ /Fio ₂ 100–174	3
PaO ₂ /Fio ₂ < 100	4
3. PEEP SCORE (WHEN VENTILATED)	
PEEP ≤ 5 cm H ₂ O	0
PEEP 6–8 cm H ₂ O	1
PEEP 9–11 cm H ₂ O	2
PEEP 12–14 cm H ₂ O	3
PEEP ≥ 15 cm H ₂ O	4
4. RESPIRATORY SYSTEM COMPLIANCE SCORE (WHEN AVAILABLE)	
Compliance ≥ 80 mL/cm H ₂ O	0
Compliance 60–79 mL/cm H ₂ O	1
Compliance 40–59 mL/cm H ₂ O	2
Compliance 20–39 mL/cm H ₂ O	3
Compliance ≤ 19 mL/cm H ₂ O	4
The final value is obtained by dividing the aggregate sum by the number of components that were used.	
	SCORE
No lung injury	0
Mild to moderate lung injury	0.1–2.5
Severe lung injury (ARDS)	>2.5

ARDS, acute respiratory distress syndrome; PaO₂/Fio₂, arterial oxygen tension to inspired oxygen concentration ratio; PEEP, positive end-expiratory pressure.

From Murray JF, Matthay MA, Luce JM, et al: An expanded definition of the adult respiratory distress syndrome. *Am Rev Respir Dis* 138:720–723, 1988.

Table 62-6 American-European Consensus Conference Definition of Acute Lung Injury and Acute Respiratory Distress Syndrome**TIMING**

Acute

OXYGENATION (REGARDLESS OF PEEP LEVEL) $\text{PaO}_2/\text{FiO}_2 \leq 300$ = acute lung injury $\text{PaO}_2/\text{FiO}_2 \leq 200$ = acute respiratory distress syndrome**CHEST RADIOGRAPH**

Bilateral opacities on frontal view

PULMONARY ARTERY WEDGE PRESSURE

<18 mm Hg when measured, or

No clinical evidence of left atrial hypertension

Table 62-7 Berlin Definition of ARDS

Mild	$\text{PaO}_2/\text{FiO}_2$	200–300 mm Hg
Moderate	$\text{PaO}_2/\text{FiO}_2$	100–199 mm Hg
Severe ARDS	$\text{PaO}_2/\text{FiO}_2$	<100 mm Hg

must be “acute”); (2) oxygenation (arterial PO_2/FiO_2 [fractional concentration of oxygen in inspired gas] <300 mm Hg, regardless of the level of PEEP, for the diagnosis of ALI to be made, and arterial $\text{PO}_2/\text{FiO}_2 \leq 200$ mm Hg, regardless of PEEP level, for the diagnosis of ARDS to be made); (3) chest radiograph (bilateral opacities seen on frontal view); and (4) pulmonary artery wedge pressure (<18 mm Hg when measured, or no clinical evidence of left atrial hypertension).

The third explication, the Berlin Definition,⁷² simply subdivides ARDS into three categories of severity: mild, moderate, and severe, based on the arterial PO_2/FiO_2 ratio (Table 62-7). Initially, so-called ancillary variables—severity of chest radiographic findings, minimum PEEP level, respiratory system compliance, and standardized minute volume—were considered for inclusion, but finally discarded. Of interest, the term “acute lung injury” was abandoned. Mortality increases successively as arterial PO_2/FiO_2 ratio worsens in mild, moderate, and severe ARDS.

Another recent method of defining and grading the severity of clinically meaningful lung damage, first in a single center⁷³ and then in 21 others,⁷⁴ is what has been called the *Lung Injury Prediction Score*, or LIPS, whose goal is to improve the early identification of patients at high risk for development of serious early or impending lung injuries. Both risk factors (predisposing conditions, such as pneumonia, severe sepsis, trauma, and aspiration) and risk modifiers (e.g., alcohol abuse, hypoalbuminemia, and use of supplementary oxygen), have each been graded numerically to yield a combined LIPS value, which has an impressively high negative predictive value (0.96 to 0.98) but a much lower positive predictive value (0.14 to 0.23).⁷⁵ A more recent study showed that diffuse alveolar damage was observed in fewer than half the patients having clinical criteria for ARDS, but was more frequent (69%) in those with ARDS lasting more than 72 hours.⁷⁶

The current working definitions all have useful attributes, but fail to link any particular clinical feature to any

particular change in the structure or function of the relevant barriers in the lungs or to the degree of pulmonary edema. What defines the ALI-ARDS continuum in a meaningful way is the altered barrier permeability to protein in the lungs, the structural damage to the lung microvascular endothelial and alveolar epithelial barriers, and the consequent excess lung water content. In the future as research studies progress, these clinical definitions may need to be supplemented with biologic markers (see next section) and pathologic findings (when available) to help categorize ALI and ARDS into more specific disease entities.

Symptoms and Signs

The clinical manifestations of pulmonary edema vary with its severity and depend on the underlying pathophysiology and the extent to which excess edema fluid has accumulated in the lungs. Characteristic symptoms comprise dyspnea, cough, and tachypnea. Wheezing, when audible, may present a problem in differential diagnosis, but patients with typical asthma generally do not have other symptoms and signs of congestive heart failure or pulmonary edema.⁷⁷ Once alveoli have flooded, the diagnosis of pulmonary edema is not subtle. Patients with alveolar edema usually have severe respiratory distress with tachypnea and cough that is often productive of frothy and sometimes blood-tinged edema fluid. Crackles and rhonchi are heard over the lung fields and wheezing may be present. The patient may be cyanotic if alveolar flooding has seriously compromised gas exchange.

Development of pulmonary edema is often slow and progressive in increased pressure pulmonary edema because the alveoli are protected by the normal safety factors (see Table 62-1). In contrast, in increased permeability edema, alveolar flooding and symptoms of respiratory distress often happen rapidly. Edema that develops suddenly (or unexpectedly) sometimes is called “flash pulmonary edema,” which usually pertains to the rapid development of high-pressure edema, after protective safety factors have been surmounted.

Because pulmonary edema is always a sign of an underlying pathologic process, its cause must be identified so that effective therapy can be directed at the underlying problem producing abnormal transvascular fluid and solute flow into the lungs. Increased pressure edema is most often caused by cardiac failure from systolic dysfunction with impaired myocardial contractility and thus is usually accompanied by a history of heart disease; manifestations include signs and symptoms of any of the many causes of chronic and acute congestive heart failure, such as coronary insufficiency, hypertension, valvular heart disease, and severe volume expansion. Elevated jugular venous pressure, cardiac enlargement, gallop rhythms, heart murmurs, arrhythmias, large tender liver, and peripheral edema almost always suggest an underlying abnormality of cardiac function. However, pulmonary edema may be the only manifestation of silent myocardial infarction or diastolic dysfunction of the left ventricle.⁷⁸

History and physical examination may also be helpful in differentiating between increased pressure and increased permeability pulmonary edema, because most patients in the latter category usually do not have signs or symptoms of underlying cardiac disease. The cause of increased

permeability edema may be suggested by a history of exposure (e.g., to toxic gases or chemicals, near-drowning, drug ingestion, trauma), the clinical setting (e.g., sepsis, pneumonia, emesis, seizures, pancreatitis), or the physical findings (e.g., chest trauma, long bone fractures, coma, shock). Because infections, including the sepsis syndrome, are the leading causes of increased permeability edema in patients, a thorough search must be made for signs and symptoms of infection. Pulmonary and intra-abdominal sources are the most common sites of involvement, and all patients should be examined carefully, with special attention being paid to abdominal, rectal, and pelvic examinations.

Diagnostic Studies

Laboratory and other diagnostic studies are often helpful but, by the time many of the results are found to be abnormal, the diagnosis is usually obvious. Appropriate cultures for microorganisms and toxicology screens of blood and urine are useful in identifying underlying causes of increased permeability edema. Examination of sputum or tracheal aspirate, bronchoscopy with protected-specimen brushing, or mini-BAL are all useful in diagnosing pneumonia in ventilated patients, even those who are being treated with antimicrobial drugs.⁷⁹⁻⁸² Lung biopsy can sometimes provide a specific diagnosis in critically ill patients,⁸³ but the results often are not helpful because lung injuries caused by diverse underlying conditions have similar histologic appearances and because specific therapies may not be available.

In the special case of pulmonary edema suspected to be caused by saltwater near-drowning, measurement of plasma magnesium level can help determine whether a patient has aspirated or swallowed seawater, or both. Severe hypermagnesemia has been reported following aspiration of ordinary seawater and, especially, highly concentrated saltwater from the Dead Sea.⁸⁴

Chest Radiographs

The plain chest radiograph is the most practical laboratory study available for the detection of pulmonary edema.^{85,86} Disadvantages are that chest radiographs are insensitive to small changes in lung water and are only semiquantitative.¹ An additional limitation is that chest radiographs are not consistently helpful in distinguishing increased pressure edema from increased permeability edema.^{85,87} These disadvantages are offset by the advantages that chest radiographs are noninvasive, inexpensive, easily repeatable, readily available, and free of serious side effects (apart from a small amount of radiation).

Before alveolar flooding, plain chest radiographs typically show distended vascular shadows (particularly in the upper lung fields), enlargement and loss of definition of hilar structures, development of septal lines (Kerley lines) (Fig. 62-5; Video 62-1, loss of peribronchial and perivascular definition or cuffing) (Fig. 62-6), and perihilar haze indicating the presence of interstitial pulmonary edema. Acinar shadows, often confluent and creating irregular, patchy increases in lung density that obscure vascular markings, indicate the presence of alveolar edema. Air bronchograms may be observed in severe edema. Because the radiographic signs of interstitial and alveolar edema are determined by gas and blood volumes and their distribution in the lungs

Figure 62-5 Frontal chest radiograph in a patient with increased pressure pulmonary edema from heart failure showing alveolar edema and bilateral consolidation. Note presence of air bronchograms. (Courtesy Michael Gotway, MD.)

Figure 62-6 Frontal chest radiograph in a 56-year-old woman with increased pressure pulmonary edema from chronic heart failure showing interlobular septal thickening. Thin linear opacities are best seen in the inferolateral thorax, particularly on the right, representing thickened interlobular septae, or Kerley B lines. See the chest CT scan for this patient in Video 61-1. (Courtesy Michael Gotway, MD.)

in addition to the presence of edema, the recognition and quantitation of edema are not precise, and the radiographic appearance of edema is strongly influenced by the lung volume at the time the film is made. The chest radiograph score is an integral part of the Lung Injury Score and the revised Berlin Definition, but the interpretation of chest radiographs is not well standardized and significant interobserver variations have been reported.⁸⁸ One recent approach for scoring the chest radiograph and accounting for atelectasis correlated well with lung weight in lungs that were studied from brain-dead potential organ donors.⁸⁹

Arterial Blood Studies

The arterial PO_2 , arterial PCO_2 , and pH are the most informative laboratory indicators of overall pulmonary function in patients with pulmonary edema. Arterial blood studies are not sensitive to early edema. Interstitial pulmonary edema does not usually affect oxygen uptake in the lungs beyond modest hypoxemia caused by ventilation-perfusion mismatching. In contrast, alveolar flooding seriously compromises gas exchange, resulting in right-to-left shunting of blood from ongoing perfusion of alveoli that cannot be ventilated because they are fluid filled or collapsed. In two studies of groups of patients with increased permeability edema from lung injury, oxygenation appeared to depend more on the vasoconstrictive ability of the pulmonary circulation—owing to the ability to reduce perfusion of damaged and edematous areas of the lungs—than on the amount of edema present.^{90,91}

In patients hospitalized for acute cardiogenic pulmonary edema, arterial PCO_2 may be low, especially in the early stages, when tachypnea results in alveolar hyperventilation; arterial PCO_2 may also be within the normal range or elevated, the latter indicating alveolar hypoventilation, which can be caused by underlying lung disease, increased metabolic production of carbon dioxide (perhaps related to increased work of breathing), increased wasted ventilation (ventilation of poorly perfused alveoli), or mechanical impairment caused by weak respiratory muscles.⁹² An elevation in the pulmonary dead space fraction in the first 24 hours after development of severe increased permeability edema identifies patients with a higher risk for survival, particularly if the dead space fraction is greater than 0.60.⁵³

When pulmonary edema is severe or the lungs have been injured, many patients develop metabolic acidosis as a result of tissue hypoxia, increased work of breathing, intrinsic lung lactate production, or all of these.⁹³ Attempts to correct acidosis with parenteral bicarbonate administration usually are not necessary; rather, the underlying cause must be identified and treated appropriately. Maintenance of a satisfactory systemic blood pressure is crucial. Respiratory acidosis caused by alveolar hypoventilation can be treated either by noninvasive ventilation or by invasive mechanical ventilation with endotracheal intubation. Metabolic acidosis can be partially corrected by alleviating hypoxemia and improving cardiac function; the possibility of underlying disease amenable to surgery (e.g., intestinal ischemia or infarction, perforation of a viscus) or pancreatitis should be considered.

Measurement of Pulmonary Edema Fluid Protein Concentration

When florid pulmonary edema is present, measurement of protein concentrations in both simultaneously collected edema fluid (suctioned through an endotracheal tube) and plasma provides a rapid, noninvasive method for distinguishing increased pressure edema from increased permeability edema.⁹⁴ Because the microvascular barrier is functionally intact in increased pressure edema, plasma proteins remain largely confined to the intravascular space, and edema fluid protein concentration is low relative to plasma protein concentration (the ratio of edema fluid to plasma protein concentration is generally <0.65). In con-

trast, in increased permeability edema, when the microvascular barrier is injured, plasma proteins leak in high concentrations into the vascular space, which raises edema fluid protein concentration high relative to plasma protein concentration (ratio of edema fluid to plasma protein concentration generally >0.75). Intermediate values (between 0.65 and 0.75) may indicate that both types of edema are present and suggest the relative contributions of each.

Measurement of the ratio of edema fluid to plasma protein concentrations has been shown to be a simple method for separating the two different pathophysiologic types in numerous reported series of patients with pulmonary edema.⁹⁵⁻⁹⁸ Three studies indicated that an increasing protein concentration in serial measurements of edema fluid in increased permeability edema was a good sign, reflecting an intact epithelial barrier and net removal of edema fluid from the alveoli.^{97,98} There is new evidence that the edema fluid to plasma protein ratio has prognostic value as well as diagnostic value.⁹⁹ Such measurements need to be correlated with the patient's clinical condition, because an increasing protein concentration in edema fluid over time might also mean that increased permeability edema was complicating what had been increased pressure edema or that the lungs were injured more severely or more extensively as time passed.

Edema fluid can be collected by inserting a standard 14- to 18-gauge catheter through an endotracheal tube and advancing it into a wedged position in the distal air spaces (similar to the procedure for wedging a fiberoptic bronchoscope). Gentle suction is applied as the catheter is slowly withdrawn, and fluid is collected in a small trap. Several attempts may be needed; if no fluid can be suctioned, the clinician should try changing the patient's position. Samples grossly contaminated with airway secretions, which have a very low protein concentration, less than 1 g/dL, such as mucus, pus, and debris, should be discarded. The protein concentration in the edema fluid and the plasma can be measured by the clinical laboratory or estimated quickly at the bedside from the protein scale of a handheld refractometer.

Standard BAL using fiberoptic bronchoscopy or mini-BAL (with a wedged suction catheter) have been used as research and diagnostic tools that may also yield useful information about the cellular biochemical and microbial composition of the air space,¹⁰⁰ but lavage is not useful as a method to measure alveolar protein concentration, because the instilled saline dilutes alveolar fluid by approximately 50- to 100-fold, depending on the method.⁶⁷

MEASUREMENT OF LUNG WATER AND BARRIER FUNCTION

In theory, measurement of the quantity of water or edema fluid in the lungs could be useful in detecting early pulmonary edema and in assessing its clinical course and response to treatment; however, no optimal technique is available. Methods in use or under investigation focus on either measurement of lung density or equilibration of tracers with water in the lungs.^{1,101} Interest in such measurements assumes that accurate knowledge about lung water content would be useful in diagnosis and would be beneficial in the treatment of patients with pulmonary edema. Recent work

with a single thermal indicator for measuring extravascular lung water has shown promise based on some studies, although the actual clinical utility has not been convincingly proven.¹⁰²

Barrier Function

Clinical distinction between increased pressure edema and increased permeability edema is difficult,^{103,104} because transvascular fluid flow into the lungs can be abnormal long before lung water content increases greatly. In theory, the two types of edema can be separated on the basis of differences in barrier function. Detection of increased transvascular fluid flow into the lungs and measurement of barrier integrity might be more helpful than measurement of lung water content in edema. A simple and practical method exists to evaluate barrier integrity (edema fluid protein concentration measurements, discussed earlier), and several methods have been studied to detect early edema and changes in barrier function. However, not one is in routine clinical use.

Biologic Markers of Lung Injury

Potential biologic markers of imminent increased permeability edema from various kinds of lung injury have been the subject of many studies and comprehensive reviews.^{67,105,106} Naturally, considerable interest revolved around finding a simple blood, urine, or BAL test that could identify patients who are destined to develop or who are already in the earliest stages of increased permeability edema, or that could predict the outcome of patients with injured lungs. To be of clinical use, such a marker would have to be both practical and inexpensive to measure as well as sensitive and specific for the detection of lung injury. An extensive search has been made for a reliable biologic marker for the detection of early or impending lung injury comparable to the decisive clinical role played by troponin measurements for diagnosing acute myocardial infarction. The long-sought diagnostic nirvana for increased permeability edema remains distant.

Several studies from multicenter clinical trials have reported the independent predictive value of some plasma markers for mortality and other clinical outcomes in patients with increased permeability edema from various lung injuries. The biologic markers of greatest predictive value are surfactant protein D,¹⁰⁷ interleukin-6 and interleukin-8,¹⁰⁸ von Willebrand factor antigen,¹⁰⁹ soluble tumor necrosis factor- α receptors I and II,¹¹⁰ intercellular adhesion molecule-1,¹¹¹ protein C and plasminogen activation inhibitor-1,^{112,113} and the receptor for advanced glycation end products.^{114,115} Because increased permeability edema follows a wide variety of insults that range in severity, and because many abnormalities detected in increased permeability edema are found in other severe illnesses of diverse etiology that do not involve the lungs, it seems unlikely that any single marker will be found that unequivocally identifies the risk or the presence of severe lung injury. Increased attention is being given to the sensitivity and specificity of combinations of markers. In support of this approach, one recent study found that combinations of three plasma biomarkers had a statistically significant better prognostic value for predicting death than the use of standard clinical predictors alone.⁶⁸

Currently, the latest intriguing biologic marker of increased permeability edema, angiopoietin-2, an endothelial growth factor and potent regulator of vascular permeability, plays a role in several different clinical conditions, including malignancies, liver failure, malaria, chronic kidney disease, heart failure, and sepsis. Heightened interest in angiopoietin-2 followed the observation that levels in patients with sepsis were “markedly elevated within the first hour of clinical care,” correlated with disease severity, rose further in patients who died, and were predictors of shock or death.¹¹⁶ Moreover, these observations have been broadened by using angiopoietin-2 values to predict the development of increased permeability edema from lung injuries in a wide spectrum of critically ill patients; combining angiopoietin-2 levels with the Lung Injury Prediction Score (described previously) improved the resulting receiver operating curve characteristics compared with each curve separately.⁷⁵ Clearly, additional studies of larger numbers of patients and outcomes are needed to bolster these observations.

TREATMENT

Treatment of pulmonary edema often requires vigorous life-saving measures, followed by specific therapy directed at the factors that led to accumulation of water in the extravascular spaces of the lungs. Rational therapy also requires an accurate diagnosis and an understanding of the nature of the underlying disease state and of the strategies that might prove useful in limiting further edema accumulation and that favor fluid removal from the lungs.^{117,118}

EMERGENCY THERAPY

Patients with alveolar edema are frequently severely ill and require immediate treatment for acute respiratory failure. The basic principles of treatment of hypoxemic respiratory failure are discussed in Chapter 100. Essential requirements for patients with pulmonary edema include preservation of the airway, and provision of satisfactory alveolar ventilation and arterial blood oxygenation. Maintenance of arterial blood pressure is indispensable. Reliable means of monitoring and sustaining oxygen saturation and blood pressure in rescue operations and ambulance travel are now widely used. Ventilatory management in patients with florid alveolar flooding and severe gas exchange abnormalities, regardless of cause, requires emergent endotracheal intubation, high inhaled oxygen concentrations, and PEEP. After stabilization, obligatory lung-protective strategies are introduced in patients with increased permeability edema (see later discussion); in contrast, increased attention is being directed at noninvasive ventilatory methods (discussed later) that hasten improvement in respiratory distress and metabolic disturbances in patients with increased pressure edema, nearly always from congestive heart failure, but have no effect on short-term mortality.

INCREASED PRESSURE EDEMA

In increased pressure pulmonary edema, the common goal of therapy is to reduce the transudation of fluid into the

lungs. Because the rate of edema formation increases exponentially with increases in pulmonary vascular pressures,⁷ hydrostatic pressure control is crucial for successful therapy. Therapy must be clearly goal oriented, responsive to the underlying pathophysiology, and frequently reassessed until the patient is stable.

General Principles

The acute recognition and management of increased pressure pulmonary edema, exemplified by congestive heart failure, has been the subject of comprehensive reviews.^{5,6,8,119,120} With increased pressure edema, the goal of therapy is to reduce the hydrostatic pressure causing edema formation in the lungs. The major objective is to achieve a net negative fluid balance without adversely affecting myocardial performance. The work of the heart must be reduced as much as possible by restricting physical activity and preventing pain and anxiety, which act to increase cardiac work by increasing sympathetic tone. As the heart fails, cardiac performance is reflexly preserved by progressive increases in vascular volumes that act to increase cardiac stroke volume and work (the Frank-Starling mechanism). This compensatory increase in preload of the left ventricle results in pulmonary venous hypertension and raises the driving pressure for fluid filtration out of the pulmonary microcirculation. As heart failure worsens, cardiac output falls, pulmonary and systemic venous pressures rise, systemic vascular resistance increases, and edema, in the lungs and in the periphery, becomes the major manifestation of compromised cardiac function.

In patients with increased pressure edema, a reduction of vascular volume and an increase in cardiac output decrease the driving pressure for edema formation. Because the normal safety factors protecting the lungs from edema driven by high filtration pressures are intact, the pressure need be lowered only toward normal. At pulmonary capillary wedge pressures less than 20 mm Hg, fluid filtration in the lungs usually should not be sufficient to cause pulmonary edema. Patients with severe cardiac failure may tolerate higher pressures—because baseline barrier permeability is lowered in the lungs and lymphatic removal capability is increased—and may require such pressures to maintain cardiac output. Therapy is directed at reducing the work the heart must perform and at increasing the heart's efficiency for the work it must do including, in some patients with severe hydrostatic pulmonary edema, the use of positive-pressure mechanical ventilation. The resolution of alveolar edema in these patients is not simply a function of lowering lung vascular pressures; other mechanisms that augment alveolar fluid clearance are important.¹²⁰

Most patients with acute pulmonary edema caused by cardiac failure have systolic dysfunction from weakened contractility, but approximately 30% of patients have diastolic dysfunction. Cardiac contraction is normal, but relaxation is impaired. Because the ventricle does not relax normally, end-diastolic pressure is increased, thereby increasing hydrostatic pressure in the lung microcirculation. Acute diastolic dysfunction producing pulmonary edema is now recognized as a common manifestation of acute myocardial ischemia or uncontrolled hypertension. Other causes include diabetes mellitus, aortic stenosis,

infiltrative cardiomyopathies, endocardial fibroelastosis, hypothermia, septic shock, elevated thoracic pressures from mechanical ventilation, and pericardial effusion. Causal or aggravating conditions should be corrected (e.g., revascularization for coronary artery disease, control of systemic hypertension). The goal of therapy in acute diastolic dysfunction is to lower elevated filling pressures (by the cautious use of diuretics and nitrates) without significantly reducing cardiac output. These patients are prone to develop hypotension in response to diuretics and nitrates because adequate cardiac output depends on elevated filling pressures in the heart. Because systolic function is normal, positive inotropic agents do not help and can actually aggravate ischemia.

In the setting of acute increased pressure pulmonary edema, it is especially important to identify and treat correctable causes of heart failure. Acute myocardial infarction, ongoing myocardial ischemia, arrhythmias, valvular lesions, systemic hypertension, ventricular septal rupture, rheumatic or other inflammatory myocarditis, digitalis intoxication, pulmonary embolism, infection, thyrotoxicosis, or severe anemia may have caused the heart to fail and must be corrected. Cardiac patients presenting with pulmonary edema may not complain of chest pain, but most of them have significant coronary artery disease, and pulmonary edema may be the only manifestation of silent myocardial ischemia.

Morphine Sulfate

The sovereign emergency therapy for acute cardiogenic pulmonary edema has long been morphine sulfate, 5 to 10 mg, or its equivalent, given intravenously slowly over several minutes, taking care to avoid hypotension. Morphine is an extremely useful drug in the treatment of heart failure, because it is a potent vasodilator as well as a central nervous system sedative and because it does not depress myocardial contractility. Its vasodilating effects can substantially reduce pulmonary capillary pressure and may improve depressed cardiac output. The work of the heart is lessened by the vasodilating, bradycardic, and sedative effects of morphine. Cautiously administered morphine usually does not cause respiratory failure or aggravate existing carbon dioxide retention associated with acute pulmonary edema, but the patient must be closely watched if he or she is not intubated and receiving assisted ventilation. Hypotension following morphine administration indicates that too much drug was given or that the intravascular volume is lower than suspected; prompt administration of naloxone (Narcan) should quickly correct the disturbance.

Decreasing Venous Return

If sophisticated medical care is not immediately available, two useful age-old remedies for increased pressure pulmonary edema can be lifesaving. First, rotating tourniquets can reduce intrathoracic blood volume—and thereby pulmonary perfusion pressure—by trapping blood in the extremities, away from the pulmonary circulation. Tourniquets, or blood pressure cuffs inflated to less than systolic pressure, are applied to three of the four extremities and rotated every 15 minutes. The purpose is to decrease venous return, not to stop all blood flow to the extremities. Care must be taken that the tourniquets are rotated and that

venous return from any extremity is not obstructed for more than 45 minutes at a time. A study of patients with left ventricular dysfunction following myocardial infarction showed trapping by tourniquets of considerable blood volume in the periphery, but variable and sometimes unfavorable effects on left ventricular function.¹²¹ Second, removal of 100 to 500 mL of bloody by phlebotomy¹²² can be used to reduce blood volume in acute pulmonary edema from congestive heart failure when the patient is not in shock and when drugs and supportive care are not immediately available.

Ventilatory Strategies

Most patients hospitalized with increased pressure edema suffer from acute or chronic heart failure and require oxygen treatment to ensure satisfactory arterial blood oxygenation. Depending on the prevailing severity of oxygen deficiency, patients with mild abnormalities may require only supplementary oxygen administered through a nasal catheter or simple mask; those with moderate oxygen deficiency may be helped with noninvasive methods of oxygen administration. Finally, profound gas exchange abnormalities require endotracheal intubation with high oxygen concentrations and elevated end expiratory pressures.

Today, after many studies, noninvasive ventilation—by either continuous positive airway pressure or noninvasive intermittent positive-pressure ventilation—has proved beneficial for the treatment of acute cardiogenic pulmonary edema; both methods cause more rapid improvement in respiratory distress and metabolic abnormalities than standard oxygen treatment.¹²³ The two types of noninvasive ventilation are similar in their clinical benefits, but have no effect on short-term mortality.¹²⁴ Properly used noninvasive ventilation spares many patients from the ordeal of endotracheal intubation, but when cardiogenic pulmonary edema is severe and worsening, intubation is immediately indicated.^{125,126}

Right Heart Catheterization

In 1970, Drs. HJC Swan and William Ganz¹²⁷ introduced the balloon flotation catheter into clinical medicine for measurements of right atrial pressure, right ventricular pressure, pulmonary artery pressure, and pulmonary capillary wedge pressure, and for assessment of cardiac output and oxygen saturation values in the right heart chambers. Pulmonary artery catheters are reasonably easy to use but training is essential. Naturally, residents and fellows, as well as seasoned attending physicians in cardiology, critical care, surgery, and anesthesiology, joined the rush to insert Swan-Ganz catheters and learn about their benefits.

The good news is that these same eager young trainees and veteran doctors did indeed learn a gigantic amount of cardiovascular and respiratory physiology that most doctors knew little or nothing about before the advent of pulmonary artery catheterization.¹²⁸ As knowledge concerning hemodynamics became everybody's business, new conceptual models for the management of acute myocardial infarction, heart failure, and cardiogenic shock based on readily obtained hemodynamic data produced new clinical insights and research rewards. Similar approaches explored the mysteries of sepsis, septic shock, and postoperative complications, and how to differentiate increased pressure from

increased permeability edema. Novel hemodynamic concepts were enhanced by the use of new and increasingly potent diuretics and vasoactive and inotropic drugs.

The bad news, of course, was that the stampede “to swan” led to considerable overuse and abuse of pulmonary arterial catheterization.¹²⁹⁻¹³³ Technical competence and professional know-how sometimes suffered, and would-be experts did not always know how to interpret the information. But the Swan-Ganz bandwagon kept rolling on and did not slow down until well into the 1990s, when authorities began to question whether or not the unrestricted use of balloon flotation catheters in patients with acute myocardial infarction was warranted. Although the outcomes of early clinical trials were not definitive, they raised considerable doubts, and it was finally recognized that pulmonary artery catheterization had no place in the routine management of acute myocardial infarction.¹³⁴

Subsequently, the prevailing certainty that monitoring pulmonary capillary wedge pressure, and cardiac output, rather than central venous pressure, would optimize both control of volume status and regulation of vasopressor and inotropic treatment was challenged and put to the test. A large NHLBI-sponsored clinical trial of 1000 patients concluded that “[pulmonary artery catheterization]-guided therapy did not improve survival or organ perfusion and complications were higher than [central venous catheterization]-guided therapy.”¹³⁵

The latest (2013) information on the use of balloon flotation catheters for adult patients in intensive care comes from the Cochrane Central Register of Controlled Trials.¹³⁶ The authors concluded “that the use of a [pulmonary artery catheter] did not alter the mortality, general [intensive care unit] or hospital [length of stay], or cost for adult patients in intensive care.” As usual, experience and clinical judgment is essential.

It must be said and emphasized—now that the old controversies have been largely clarified—that several incontrovertible indications for Swan-Ganz catheterization endure unchallenged and remain commonly employed, particularly in the diagnosis and monitoring of cardiovascular diseases.¹²⁸ Alternative methods of hemodynamic monitoring, such as the Pulse Index Continuous Cardiac Output device,¹³⁷ are being designed and evaluated, but there remains an important role for balloon flotation catheters for critically ill adult patients.

Specific Pharmacologic Therapy

After emergency treatment has been instituted and the patient's condition stabilized, three major therapeutic options—vasodilators, diuretics, and inotropic agents—need to be considered and administered when appropriate. The goal of therapy with these agents is to lower the hydrostatic pressure at the filtration sites in the pulmonary vascular bed while maintaining adequate systemic delivery of oxygen. The choice of therapy is dictated by the patient's condition and the cause of the pulmonary edema.

Vasodilators. Depending on their specific therapeutic indications, vasodilators are used for hypertension, congestive heart failure, and angina. Several medications are available, usually in combination and usually as part of a long-term treatment regimen. Vasodilators are useful

pharmacologic agents for the treatment of acute increased pressure pulmonary edema, because their effects happen rapidly, usually in minutes. Through dilation of veins, vascular capacitance is increased and blood is redistributed peripherally, thereby lowering the driving pressure for fluid filtration in the lungs; through dilation of arteries, systemic vascular resistance (cardiac afterload) falls, cardiac output and stroke volume increase, and the heart works more efficiently. In addition to morphine, three classes of vasodilators may be useful in pulmonary edema: venodilators (e.g., nitrates), arteriolar dilators (e.g., phentolamine, hydralazine), and mixed dilators (e.g., nitroprusside).

The most common side effects of vasodilators such as dizziness, especially when standing, are related to low blood pressure. Tolerance to vasodilators may require revision of long-standing therapy.

Diuretics. Patients with symptoms of pulmonary edema, especially from increased vascular pressure, usually benefit from administration of diuretic agents, a standard means of initial therapy.¹³⁸ These drugs may exert a modest immediate effect by increasing venous capacitance and decreasing the relative perfusion of flooded alveoli (acting as vasodilators), but their principal mechanism of action is to increase sodium and water excretion by the kidneys.¹³⁹ The resultant diuresis causes a decrease in left ventricular volume and pressure and thereby a reduction in left atrial pressure and the pressure at the filtration sites in the lungs. Among the potent loop diuretics administered by slow intravenous injection, furosemide is highly effective and generally regarded as the agent of choice. Dozens of different dosage regimens of furosemide have been and are still being used to treat symptomatic patients with pulmonary edema from acute congestive heart failure. One such regimen consists of a loading dose of 40 to 80 mg followed by a continuous infusion at 10 to 20 mg/hr; if there is no response in an hour, the loading dose is repeated and the infusion rate is doubled. Equivalent doses of other loop diuretics (bumetanide, torsemide, or ethacrynic acid) have essentially the same effects.

Decades of clinical experience have documented that intravenous administration of loop diuretics nearly always result in prompt diuresis and symptomatic relief. Nevertheless, information about safety and efficacy is lacking and optimal use of diuretics in heart failure management needs much further study and improvement.¹⁴⁰

If the patient is hypotensive or in frank shock, diuretics are seldom of benefit, because poor renal perfusion limits any effects they might have on kidney function. In this circumstance, continuous venovenous ultrafiltration can reduce intravascular volume even in patients who require vasopressors for blood pressure support.

If the patient has severely diseased kidneys, diuresis may not be an option. In this circumstance, continuous arteriovenous hemofiltration with or without counter-current dialysis¹⁴¹ or venovenous ultrafiltration¹⁴² should be considered. These techniques represent considerable advances over traditional hemodialysis, which was often impossible in hemodynamically unstable patients (especially those with low cardiac output or hypotension), and peritoneal dialysis, which was both slow and poorly tolerated. Hemofiltration can be instituted, maintained, and managed suc-

cessfully by well-trained intensive care unit nurses and physicians, and it is not complicated by hypotension because the circuits have small volumes and pressures are low. Considerable fluid (<200 to 300 mL/hr) can be removed when needed, with the amount being titrated to the patient's cardiovascular status.

Inotropic Agents. Patients with cardiogenic shock and other cardiac catastrophes that lower systemic blood pressure often require inotropic agents as a temporary life-saving measure. In quite a different therapeutic category, patients with systolic heart failure and pulmonary edema with impaired cardiac contractility were at one time also thought to benefit from inotropic agents by increasing cardiac output and lowering the driving pressure for fluid filtration in the lungs. Although the use of pharmacologic agents to improve myocardial contractility seems rational, current opinion states that "inotropic therapies in the [systolic heart failure] population have universally failed to live up to their expectations."¹⁴³ Palliative inotropic treatment has its occasional indications, but other options such as combination implantable cardioverter-defibrillator and cardiac resynchronization may also provide benefits.¹⁴⁴

When present, increased pressure pulmonary edema is an important associated feature of impaired myocardial contractility, has proven difficult to treat, and has a poor prognosis; individualized diagnostic fine-tuning may transiently improve clinical outcome, but results remain modest at best. Older methods, however, are being supplanted by advanced techniques of coronary reperfusion, mechanical support with intra-aortic balloon pumps or ventricular-assist devices, expanded use of extracorporeal membrane oxygenators for severe respiratory failure, and improvements in heart and/or lung transplantation.

INCREASED PERMEABILITY EDEMA

As already emphasized, the strategy for managing patients with increased permeability pulmonary edema caused by various types of severe lung injury differs from that for patients with increased pressure pulmonary edema in two crucial respects: first, the endothelial and epithelial barriers are damaged in permeability edema, whereas they are usually normal in high-pressure edema; and second, when barriers are damaged, edema develops even at low driving pressures. The goals of therapy (Table 62-8) are to treat the underlying cause of acute lung damage, to provide support while the repair phase begins, to use a lung-protective ventilator strategy that will not worsen the lung injury, and to reduce as much as possible the driving pressures for fluid movement across the injured barriers into the lungs.

General Principles

The cause of lung injury may not always be apparent, and when the cause is not obvious, it should be assumed to be infection: the most common treatable underlying cause of increased permeability edema. Although the patient is often seriously ill, diagnostic studies must be performed to identify a possible source of infection, so that appropriate drainage and antimicrobial therapy can be instituted. Plain chest radiographs are seldom helpful. Abdominal sonograms and CT scans can be diagnostically useful. Sepsis

from intra-abdominal infection is common and may be especially difficult to identify. Many of these infections require surgical drainage if antimicrobial drug therapy is to be effective. Because specific therapy for increased permeability is not usually available—unless the cause is a treatable infection—supportive therapy is extremely important. The initial concerns are to support ventilation and circulation. Patients with increased permeability edema may be hemodynamically unstable, and ventilatory support can be complicated by hypotension or frank shock; PEEP, which is usually required for adequate oxygenation, may compound the problem by impeding venous return to the heart and decreasing cardiac function.

Patients with low pulmonary capillary wedge pressures (<10 mm Hg) or central venous pressure (<4 mm Hg) and systemic hypotension require fluid resuscitation to support blood pressure and end-organ perfusion. If the patient has active, ongoing blood loss or the hemoglobin concentration is low (<7 g/dL), packed red blood cells are effective, not only to expand intravascular volume and restore blood pressure, but also to increase the oxygen-carrying capacity of the blood. Patients who are not bleeding and who have normal hemoglobin concentrations should be resuscitated with crystalloid solutions. Because the barriers restricting colloid movement from the vascular space into the lungs are not functioning normally in injured lungs, protein osmotic pressure differences favoring fluid movement into the vascular space cannot be established in the lungs; therefore there is no advantage to fluid resuscitation with colloid solutions.

Patients with hypotension that does not respond to fluid resuscitation or who have normal (>10 mm Hg) or elevated pulmonary capillary wedge pressure require vasopressors or positive inotropic agents. For patients with septic shock, generalized vasodilation resulting in low systemic vascular resistance is the major hemodynamic abnormality.¹⁴⁵ Nor-epinephrine is the most commonly used vasopressor to support blood pressure, but dopamine is also widely used.

Aggressive hemodynamic support of critically ill patients can be detrimental if the complications of therapies become more harmful than the underlying disease itself. Strategies to increase systemic oxygen delivery (e.g., with inotropes, intravascular fluids, and blood transfusions) or to achieve

supranormal values for the cardiac index or normal values for mixed venous oxygen saturation did not improve mortality when applied to all critically ill patients, but did improve outcome in patients with sepsis who were treated very early in their course.^{146,147} One ARDS Network clinical trial showed that, in patients without shock, as defined by lack of need for vasopressor treatment, a strategy to restrict fluids to reduce intravascular pressures improved clinical outcomes by reducing the duration of mechanical ventilation in patients with ALI; of note, pressure measurements from both central venous and pulmonary artery catheters provided equally useful guidelines for fluid restriction, but pulmonary artery catheterization was associated with significantly increased complications.¹⁴⁸

A multicenter, randomized, controlled clinical trial of transfusion requirements in critically ill patients with euvolemia after initial treatment compared a restrictive strategy of transfusing red blood cells if the hemoglobin concentration dropped to less than 7 g/dL versus a more liberal strategy of maintaining hemoglobin concentration greater than 10 g/dL. Restricting transfusion requirements to maintain hemoglobin concentration at 7 to 9 g/dL was at least as effective and was possibly superior to the strategy of giving transfusions to maintain hemoglobin concentration at 10 to 12 g/dL; the sole possible exception to this policy included patients with active coronary ischemic syndromes, such as acute myocardial infarction and unstable angina.¹⁴⁹

Lung-Protective Ventilator Strategies

In experimental animals, ventilation with high tidal volumes increases vascular filtration pressures and produces stress fractures of microvascular endothelium, alveolar epithelium, and basement membrane.^{150,151} The resulting injury appears to be due to the combination of large tidal excursions at high lung volumes coupled with elevated airway pressures: so-called *volutrauma*. Because the evidence from animal studies and small clinical trials provided compelling experimental rationale,^{152,153} investigations were performed to test the potential benefit of lower tidal volumes and reduced airway pressures versus standard (high) tidal volumes and elevated pressures. A large NHLBI-sponsored multicenter trial was stopped prematurely after the enrollment of 861 patients with well-defined ALI-ARDS. The trial compared “traditional” ventilator management using initial tidal volumes of 12 mL/kg of ideal body weight with plateau pressures of 50 cm H₂O or less, with lower tidal volumes of 6 mL/kg with airway plateau pressures limited to 30 cm H₂O or less: “Mortality was lower in the group treated with lower tidal volumes than in the group treated with traditional tidal volumes—31% vs. 39.8%, $P = .007$ —and the number of days without ventilator use during the first 28 days after randomization was greater in this group—(mean \pm SD), 12 ± 11 vs. 10 ± 11 ; $P = .007$.”¹⁵⁴

The results of this seminal trial and several follow-up studies have transformed the management and outcome of patients with ARDS,¹⁵⁵⁻¹⁵⁸ and are being successfully applied to critically ill patients without ARDS.^{159,160} The protocol for implementing the lung-protective ventilatory strategy is detailed in Table 100-3 and further discussed in Chapter 100.

Interestingly, results from an Italian study showed that a low tidal volume strategy in ARDS patients attenuated inflammatory responses in both the lungs and bloodstream, as measured by a reduction in neutrophil and cytokine concentrations in BAL fluid and a reduction in cytokines in circulating blood.¹⁶¹ Other studies have confirmed that low tidal volume lung-protective ventilation is associated with reduction in inflammatory markers in the lung.¹⁶² In addition, alveolar epithelial injury is probably reduced, considering the decline in surfactant protein D levels (a type II epithelial cell marker) and the receptor for advanced end glycation product (a type I epithelial cell marker) in the plasma of patients treated with the lung-protective ventilatory strategy.^{115,163}

In addition to use of the lung protective ventilatory strategy, several adjuncts in small numbers of patients have been proposed to supplement treatment of critically ill patients, including prone positioning,¹⁶⁴ extrapulmonary gas exchange (oxygenation, carbon dioxide removal, or both), liquid ventilation, tracheal gas insufflation, permissive hypercapnia, and high-frequency ventilation. Additional discussion of these modalities is provided in Chapter 100.

Specific Pharmacologic Therapies

Several therapeutic agents, which are listed in Table 62-9, have been studied in patients with various forms of lung injury and sepsis. None of these agents have shown any benefit on mortality in large-scale, prospective, randomized, controlled clinical trials, including a recent trial of statins in ARDS.^{164a}

Whether or not newer anti-inflammatory therapies will be useful in patients with increased permeability edema from damaged lung barriers remains an important question. Although inflammatory reactions can damage tissue, it is important to remember that inflammation plays an important beneficial role in the elimination of invading microorganisms. Because inflammatory pathways are redundant, blocking any one inflammatory mediator (or even multiple mediators) may have little or no effect on the overall inflammatory response. If the mechanisms of lung injury differ after various clinical events, the application of therapy directed at one particular mechanism would not be appropriate until most or all of the underlying mechanisms have been recognized and treated successfully.

Table 62-9 Therapeutic Agents Tested in Increased Permeability Pulmonary Edema^{164a}

Pentoxifylline
Beta-adrenergic agonists
Statins

Corticosteroids. Of all the possible pharmacologic agents used to treat critical lung injuries, corticosteroids have the longest history. Despite a seemingly compelling rationale for their use in the setting of increased permeability edema from sepsis, four separate prospective, randomized, double-blind, placebo-controlled trials of high-dose methylprednisolone therapy failed to show any benefit.¹⁶⁵ Corticosteroid therapy did not prevent the development of well-characterized ALI or decrease its incidence in patients with the sepsis syndrome; neither did it hasten the reversal of ARDS, lower mortality, or improve respiratory function. Moreover, use of corticosteroids was associated with both a greater 14-day mortality rate in patients who developed critical lung injury and an increased frequency of associated infections. Corticosteroids also were ineffective in the sepsis syndrome and may have caused harm.¹⁶⁶

One exception may be the *fat embolism syndrome*. A prospective, randomized, double-blind, placebo-controlled trial of corticosteroid treatment in 64 patients with long bone fractures showed that high-dose methylprednisolone effectively prevented the development of the fat embolism syndrome.¹⁶⁷ Fat embolism is an uncommon clinical syndrome that is usually described in single case reports from orthopedists; corticosteroid treatment has not been routinely used and thus far a large-scale multicenter, randomized trial does not seem warranted.

The generally disappointing results of corticosteroid trials in patients with early or impending lung injury have not discouraged further investigations; rather, ongoing studies indicate that corticosteroids might be beneficial in subsets of patients or when given at a particular time (e.g., during the proliferative phase) or for a more sustained period.¹⁶⁸ Results of studies of corticosteroid therapy late in the course of ARDS (so-called rescue therapy) were encouraging, and a small (24-patient), randomized, double-blind, placebo-controlled clinical trial in patients with severe ARDS whose Lung Injury Score had failed to improve by the seventh day of respiratory failure showed improvement in lung injury and other organ dysfunction scores, as well as reduced mortality in treated patients.¹⁶⁹ However, an NHLBI-sponsored trial of corticosteroid therapy (methylprednisolone 2 mg/kg) beginning on day 7 to 21 of ARDS showed no reduction in 60- or 180-day hospital mortality in patients treated with corticosteroids compared with placebo.¹⁷⁰ In addition, there were important neuromuscular complications in patients treated with methylprednisolone. One study suggested potential benefit with steroids in severe lung injury although the design of the trial was suboptimal.¹⁷¹

Neuromuscular Blocking Agents. Experience to date has been limited and randomized clinical trials inconclusive concerning both the efficacy of neuromuscular blocking agents in the treatment of ARDS and their association with intensive care unit-acquired muscular weakness. In 2010, a randomized-controlled trial showed improvement in the adjusted 90-day survival and time off the ventilator in patients receiving cisatracurium compared with placebo.¹⁷² A new systematic review and meta-analysis, which included three trials, all from the same French research group, reevaluated the potential benefit of 48-hour intravenous infusions of cisatracurium besylate; short-term infusion of

this neuromuscular blocking agent significantly improved mortality rate and lowered the risk for barotrauma, but had no effect on the length of mechanical ventilation among survivors.¹⁷³ Data on risk of intensive care unit-acquired weakness were inconclusive. Further studies are needed to settle this pending issue.

OUTCOME

The outcome of patients with pulmonary edema depends on which of the two major pathophysiologic categories of edema formation is involved. Until recently, much less was known about the resolution of pulmonary edema than about its formation. Water—and any extravasated proteins and cellular debris—must be removed from the alveoli and the interstitial spaces to restore the lungs to their pristine, healthy condition. Edema fluid clears from the lungs via five routes: lymphatics, airways, blood vessels, pleural space, and mediastinum; in contrast, cellular debris and particulate matter must be removed from the alveoli by macrophage uptake or through the airways.

RESOLUTION OF PULMONARY EDEMA

The considerable advances in our understanding of the clearance of fluid and solute from the alveoli have been the subject of several reviews.^{2,174,175,175a} Active sodium and chloride transport across the alveolar epithelial barrier into the interstitium drives edema fluid removal from the air spaces (see Chapter 9). The uninjured alveolar epithelium has a remarkable ability to clear fluid from the air spaces rapidly: for example, serial edema fluid protein concentration measurements relative to simultaneous plasma protein concentrations in a saltwater near-drowning patient showed that 50% to 60% of the excess alveolar fluid in the lungs was removed over the course of just 4 hours.³⁸ In experimental studies in rabbits, instillation of 4 mL/kg of seawater into the lungs resulted in a 300% increase in alveolar fluid volume in less than 5 minutes—owing to the movement of mainly pure water driven by osmotic forces from the plasma into the hyperosmolar (881 ± 29 mOsm) instillate—80% of which was cleared from the alveoli in 6 hours.³⁹

Equivalent volumes of iso-osmotic (292 ± 6 mOsm) saline instilled into rabbit lungs were cleared at a similar rate. In neither circumstance was there evidence of injury to the alveolar epithelial barrier, which is more resistant than the endothelial barrier to a wide range of injuries, including ischemia, alveolar and intravenous endotoxin and bacteria, intravenous oleic acid, acid aspiration, saltwater aspiration, hyperoxia, intratracheal bleomycin, septic and hypovolemic shock, and rewarming after severe hypothermia. Even after mild to moderate alveolar injury, the capacity to transport salt and water is often preserved. In severe injury, however, when the barrier is disrupted, the capacity to clear edema is lost, and the vascular endothelium becomes the limiting barrier between the vascular system and the air spaces. Clinically, the capacity to remove some alveolar edema fluid—as indicated by increase in the edema fluid to plasma protein concentration ratio in the first 4 to 12 hours after the development of increased permeability edema—is a favorable prognostic finding associ-

ated with a mortality of only 20%. In contrast, the inability to resorb alveolar edema fluid early in the course of severe lung injuries was associated with a mortality of nearly 80%.⁹⁷ Of interest, a larger and more recent study confirmed these results.⁹⁸ Thus the functional capability of the alveolar epithelial barrier in acute increased permeability edema may be a useful prognostic index, perhaps because it serves as a marker of the severity and extent of lung injury.

The barrier function may also be manipulated in certain settings. Lung Na^+ , K^+ -ATPase activity was increased in rats recovering from experimental thiourea-induced increased permeability pulmonary edema.¹⁷⁶ Moreover, alveolar fluid clearance can be increased by salmeterol in uninjured ex vivo human lung,¹⁷⁷ and experimental studies have shown that alveolar fluid clearance can be increased pharmacologically (e.g., by catecholamines), even in the presence of increased permeability edema with alveolar flooding.² These observations raise the potential of therapy to hasten the resolution of alveolar edema, although an increase in alveolar clearance requires an intact alveolar epithelial barrier.

Because clearance of protein from flooded alveoli is much slower (1% to 2%/hr) than clearance of protein-free fluid (10% to 20%/hr),^{178,179} the protein left behind becomes concentrated. The increase in protein concentration in the alveoli as protein-free fluid is resorbed does not slow fluid clearance, because precipitated protein exerts no osmotic pressure and the concentration of soluble macromolecules is too small to counteract the differences in ion concentration resulting from transepithelial transport. Removal of edema fluid from flooded alveoli may be slowed if the fluid clots, which can be seen especially when lung vascular permeability is increased. Edema fluid may clot because, following extravasation of plasma into the air spaces, the clotting system may be activated by surfactant or macrophage-derived procoagulants.

Fluid cleared from alveolar spaces into the alveolar interstitium can leave the lungs by flowing into the lymphatic capillaries or by moving down the prevailing pressure gradient into the loose peribronchovascular connective tissue spaces or directly into the pleural space. Large amounts of fluid in the air spaces may be partially cleared into peribronchovascular cuffs through the hypothesized “leaky” terminal-airway epithelium,^{180,181} leaving alveolar fluid and solute behind to be cleared more slowly through the more impermeable alveolar epithelium.

Most of the interstitial water in pulmonary edema is in the peribronchovascular loose connective tissue spaces rather than in the alveolar walls. Because the lymphatic capillaries are arranged to drain only the alveolar wall interstitium, this route for edema removal is not available for most interstitial water. A study in goats showed that lung lymph originated mainly from alveolar wall interstitial fluid, and the contribution of the lung lymphatic system to the clearance of interstitial edema in bronchoalveolar cuffs and interlobular septa was small. The maximum possible contribution by lung lymphatics to the clearance of interstitial edema liquid was less than 10%, and airway loss of liquid by evaporation was about twice the rate of lymphatic clearance.¹⁸² In a study of in situ perfused sheep lungs with experimental low- and high-protein pulmonary edema, during recovery from pulmonary edema, interstitial liquid

was resorbed into the circulation in inverse proportion to its protein concentration, and only a very small fraction of interstitial edema was cleared by the lung lymphatics during recovery from either type of edema.¹⁸³ Some fluid from the loose peribronchovascular interstitium may drain directly into the bloodstream by crossing the walls of blood vessels in the lungs.

A study of isolated sheep lungs made edematous by raising vascular pressures showed that the primary route of edema clearance was by vascular resorption; 60% of filtered water was cleared over 3 hours, 42% by reabsorption into the bloodstream and 18% by lymphatic, pleural, and mediastinal drainage.¹⁸⁴ Edema may also drain into the pleural space. Pleural effusions are fairly common in increased pressure pulmonary edema—found in about 25% to 50% of patients and usually on the right side when unilateral—but are present in increased permeability as well—in about 35% of patients.¹⁸⁵⁻¹⁸⁷ Formation and removal of pleural effusions are discussed in detail in Chapter 79. As much as 25% to 30% of pulmonary edema fluid may leave the lungs through the pleural space.^{186,188} A significant portion of the interstitial edema probably follows the prevailing pressure gradient in the lungs to drain into the mediastinum to be removed by neighboring lymphatics.

Short-term alveolar protein clearance appears to proceed primarily by paracellular diffusion and is size dependent.⁶ Most proteins are cleared intact rather than being degraded into smaller fragments. The general consensus is that transcytosis (transport via vesicles) is not a major mechanism for clearing bulk quantities of albumin or other proteins from the alveolar space. Over the long term, cellular mechanisms, principally phagocytosis and catabolism by macrophages, account for most protein clearance from the alveolar space.⁵⁶ Insoluble, precipitated proteins are removed in this way. Macrophages are also ultimately responsible for removing senescent and dead PMNs and other debris. The small ciliated surface area of the distal air spaces seems to indicate that the mucociliary route could account for only a minor fraction of alveolar protein clearance, although proteins might reach the mucociliary escalator along currents in the alveolar fluid layer. Even so, removal would be very slow: the half-time for mucociliary clearance of particles from the alveolar space is more than 4 weeks. Complete clearance of alveolar protein from pulmonary edema by any route is slow.⁶

Little is known about the mechanisms and signals that regulate endothelial barrier function or how increased endothelial permeability returns to normal¹⁸⁹; on the other hand, the mechanisms for resolution of lung inflammation are beginning to be understood.⁵⁶

Increased Pressure Edema

The outcome of increased pressure pulmonary edema is determined by the underlying cause and the treatment used to correct it. Because the great majority of cases of increased pressure edema are caused by heart disease, outcome is largely determined by the patient's underlying cardiac function. Patients with pulmonary edema uncomplicated by acute myocardial infarction do reasonably well with an annual mortality rate of less than 10%.¹⁹⁰ However, when acute myocardial infarction supervenes, the prognosis

worsens, although coronary vascular reperfusion therapy, using thrombolytics and coronary angioplasty with stent placement, has considerably improved survival. Typically, patients who recover from increased pressure pulmonary edema caused by chronic congestive cardiac failure require long-term outpatient management aimed at preventing recurrent episodes.¹⁹¹

Some patients develop increased pressure pulmonary edema from noncardiac causes. Most cases are iatrogenic, being related to excessive, sometimes inadvertent, volume overload or to the use of drugs such as cocaine that impair cardiac function.¹⁹² Pulmonary edema associated with congenital or acquired heart disease is an uncommon but important problem in pregnancy, but pulmonary edema without heart disease is, perhaps, even more frequent. As discussed in Chapter 96, pregnancy complicated by pulmonary edema is occasionally caused by tocolytic treatment,¹⁹³ fluid overload, or preeclampsia.

Increased Permeability Edema

The outcome of increased permeability pulmonary edema from both ARDS and forms of milder lung injury is determined by its underlying cause and extent of lung injury, the presence of comorbidities, and the particular treatment strategy employed. The reported mortality rates range from 20% to 60% depending on the specific etiologic factor, but yearly ARDS mortality rates reported from a single institution in the period between 1983 and 1993 showed a significant decrease in patients younger than 60 years and in those with sepsis syndrome.¹⁹⁴ Recent trends in ALI mortality from 1996 through 2005 in 2451 mechanically ventilated patients enrolled in the NHLBI ARDS Network showed “clear temporal improvement in survival”; in 1996-1997, mortality was 35% and steadily declined to a low of 26% in 2004-2005.¹⁹⁵ Furthermore, 60-day mortality decreased even further to 22% in adult patients in the most recent ARDS Network clinical trials, despite an increased severity of illness.¹⁹⁶ Using the NHLBI-consensus definition in patients from Iceland, the incidence of ARDS almost doubled from 1988 to 2010, whereas hospital mortality decreased from 50% in 1988-1992 to 33% in 2006-2010; conversely, the 10-year survival of ARDS patients was only 68% compared with 90% in the reference population.¹⁹⁷

Patients with sepsis have significantly higher mortality rates than patients with other clinical disorders associated with the development of increased permeability edema.¹⁹⁸ Mortality, also, is much higher in patients with chronic liver disease¹⁹⁹ or with histories of chronic alcohol abuse than in other predisposing conditions. Besides damaging the liver, chronic ethanol ingestion may reduce alveolar type II cell glutathione content and impair surfactant synthesis and secretion.²⁰⁰ In general, mortality from ARDS increases with increasing age, which conforms to both data and expectations.²⁰¹ Patients with uncommon self-limited causes of injury, including venous air and fat embolism, isolated lung contusion and other trauma, massive blood transfusions, postictal pulmonary edema, and heroin pulmonary edema (Fig. 62-7), and those with milder degrees of edema have a greater chance of survival and edema often clears rapidly.

As pointed out, since at least during the 1980s, survival from increased permeability has steadily improved, but

Figure 62-7 Frontal chest radiographs in a 22-year-old patient with heroin-induced increased permeability edema. Frontal chest radiograph performed at the time of presentation (**A**) shows patchy bilateral peribronchial thickening and consolidation, somewhat more prominent and nodular on the right. The vascular pedicle is narrow, and no features suggestive of volume overload are present. Frontal chest radiograph 24 hours later (**B**) shows complete clearing of lung opacity. Increased permeability edema may resolve rapidly if the initiating agent of lung injury is transient and mild and the chronic phase of parenchymal lung injury (type II cell hyperplasia, fibrosis, connective tissue deposition, vascular remodeling) does not develop. (Courtesy Michael Gotway, MD.)

long-term sequelae pose increasing problems. In decades past, based on short-term follow-up studies, survivors of ARDS seemed to do well; many had normal chest radiograph results, minimal or no complaints of dyspnea on exertion, normal lung volumes and airflow measurements, and normal resting and exercise arterial blood gas findings, including shunt fraction. Although the numbers of patients and the duration of follow-up may have left some doubt about the final outcome, an apparent paradox has taken place. Mortality from ARDS has clearly decreased over the past decades, whereas long-term survivors seem to have suffered worsening physical, cognitive, and mental health.

The post-ARDS return of pulmonary function test results to normal or near-normal values may, in fact, have obscured a significant deterioration of health-related quality of life. Disabling symptoms from muscle wasting, weakness, and fatigue were consistent with reduced 6-minute walk distances that changed little during the first 12 months in previously high-functioning, mostly young subjects.⁵⁷ Cognitive and emotional function was significantly impaired in “all” surviving post-ARDS patients at hospital discharge, 78% of whom remained symptomatic after 12 months. Furthermore, psychological sequelae such as anxiety, depression, and posttraumatic stress disorder persisted in 20% to 40% of survivors.⁵⁸ The roles played by treatment of ARDS with corticosteroids and neuromuscular blocking are not clear-cut, but neither agent appears to be a major factor.

Healing involves a fibroproliferative response in a subset of ARDS survivors, which seems to begin early in the course of increased permeability edema,²⁰²⁻²⁰⁴ perhaps as a consequence of ventilator-induced lung injury before the era of lung-protective ventilation²⁰⁵ (Video 62-2). How much of this problem is due to disease and how much to treatment is not known, but a fibroproliferative reaction portends a poor prognosis, either increased mortality or prolonged ventilation dependence. It might also be possible to accelerate reconstitution of alveolar structure in injured lungs; for example, keratinocyte growth factor (fibroblast growth factor-7),²⁰⁶ has been effective in several preclinical models of ALI²⁰⁷ and is now being tested in a phase 2 trial. More information about repair and healing should open new pos-

sibilities for therapy, including a better understanding of how lung progenitor cells may play a role in lung repair and regeneration.^{208,209}

OVERVIEW

Among the significant advances since the late 1960s has been the acquisition of important new knowledge concerning the physiology of fluid, solute, and protein transport in healthy and diseased lungs. Pulmonary edema—the abnormal accumulation of extravascular fluid in the lung—is a pathologic state that arises when fluid is filtered into the lungs faster than it can be removed. The many causes of pulmonary edema have been grouped into two main pathophysiologic categories: (1) increased pressure edema that results from an increase in the hydrostatic or protein osmotic forces (or both) that act across the barriers that normally restrict movement of fluid and solutes in the lungs; (2) increased permeability edema that results from damage to the normal barrier properties of lung endothelium and/or epithelium. Although these two different types of pulmonary edema share many features, they can usually be distinguished clinically and they have different treatment requirements and prognoses; differentiation is made possible by careful clinical, radiologic, and physiologic evaluation, but both increased permeability and increased pressure edema often coexist.

Increased pressure pulmonary edema typically has one of two cardiac origins, either from new-onset acute myocardial infarction or from inadequately treated and/or refractory heart failure, most commonly caused by coronary heart disease, but many other sources are possible. Revascularization techniques for acute and chronic manifestations of coronary heart disease have dramatically improved prognosis and long-term outcome. Acute cardiogenic pulmonary edema is becoming scarce and should become even scarcer. However, more attention is currently being paid to the acute complications of cardiovascular disease than to its chronic therapeutic requirements. Nevertheless, therapy of chronic heart disease has huge clinical payoffs and much more should be done to ensure satisfactory blood pressure control, regulate dyslipidemias, and manage anticoagulants, starting with aspirin.

There have been major advances in the treatment of increased permeability edema, largely due to the successful early application of lung-protective ventilatory strategies in patients with clinical lung injury. A low tidal volume (6 mL/kg ideal body weight) coupled with a plateau pressure limit (<30 cm H₂O) is still the only therapy proven to reduce mortality in patients with well-defined ALI and ARDS. Short-duration infusion of neuromuscular blockade agents show promise in severe ARDS, but further studies are needed for confirmation. New insights into the pathogenesis of various causes of increased permeability pulmonary edema suggest that other therapies may also prove to lower mortality in this common syndrome of severe acute respiratory failure.

Key Points

- The two main categories of pulmonary edema are (1) increased pressure edema from an increase in the hydrostatic or protein osmotic forces (or both) that act across the barriers that normally restrict movement of fluid and solutes in the lungs and (2) increased permeability edema from damage to the normal barrier properties of lung endothelium and/or epithelium.
- An evaluation of the cause of pulmonary edema should include a detailed history, thorough physical examination, and selected laboratory data, including a chest radiograph, electrocardiogram, cardiac enzymes, and, in some patients, microbiologic cultures, an echocardiogram, and, occasionally, pulmonary artery catheterization.
- Increased permeability pulmonary edema may be complicated by the presence of elevated pulmonary intravascular pressures, especially from coexisting cardiac failure or volume overload.
- Treatment for cardiogenic pulmonary edema should include the immediate administration of supplemental oxygen, morphine (usually), and pharmacologic measures to reduce preload.
- The diagnosis of increased permeability pulmonary edema should always include a thorough search for a treatable infection.
- Patients with increased permeability edema and, increasingly, other forms of ventilatory failure, require intubation and lung-protective ventilation, using 6 mL/kg tidal volume and less than 30 cm H₂O plateau pressure.

Cryptogenic Organizing Pneumonia

Idiopathic Lymphocytic Interstitial Pneumonia

Idiopathic Pleuroparenchymal Fibroelastosis

INTRODUCTION

The term *interstitial lung disease* (ILD), in general, implies the clinical manifestation of inflammatory-fibrotic infiltration of the alveolar walls (septa) resulting in profound effects on the capillary endothelium and the alveolar epithelial lining cells (Fig. 63-1). Under normal conditions, small numbers of interstitial macrophages, fibroblasts, and myofibroblasts reside within the interstitium. Other components of the interstitium include the matrix proteins of the lung, consisting of collagen-related macromolecules and the noncollagenous proteins such as fibronectin and laminin.

In many of ILDs, interstitial fibrosis follows injury to the gas-exchanging units. This injury increases alveolar permeability, enabling the serum contents to enter the alveolar spaces resulting in airspace abnormalities in addition to the interstitial changes. Fibroblastic proliferation and excessive

collagen deposition, the histologic hallmarks of ILD, either result directly from the initial injury, from the inflammatory cell response that releases proinflammatory and profibrotic cytokines, or from the regenerative and reparative processes taking place at the epithelial and endothelial surfaces. Moreover, fibroblastic proliferation and collagen accumulation also takes place within airway and alveolar lumina and walls of small airways (alveolar ducts, respiratory bronchioles, and terminal bronchioles).

ILDs include many entities that injure the lung parenchyma, producing diseases with similar clinical, radiographic, and physiologic features. Some develop in the setting of other conditions, such as connective tissue disease; others are idiopathic. The primary goal of the clinician is to determine the cause or underlying disease whenever possible and, if not, at least a diagnosis that allows prognostication and a management plan.

Figure 63-1 Schematic depiction of the lung parenchyma surrounding an alveolar space. The major cells that line and lie within the interstitial space are identified.

CLINICAL AND HISTOLOGIC CLASSIFICATION OF INTERSTITIAL LUNG DISEASE

The exact prevalence and incidence of ILDs are unknown. Studies suggest a prevalence of 81/100,000 for men compared with 67/100,000 for women.^{1,2} Similarly, the overall incidence of ILD is slightly more common in men (32/100,000/yr) than in women (26/100,000/yr) and increases with age. For example, among men and women 75 years of age or older, the prevalence of *idiopathic pulmonary fibrosis* (IPF) was 250/100,000 and the incidence was 160/100,000/yr.¹

ILDs can be classified according to clinical, histopathologic, or radiologic parameters. A clinical classification of ILDs is shown in [Table 63-1](#).³ Although the diagnosis of ILD due to occupational exposure, a medication, or a connective tissue disease may be obvious, primary and idiopathic ILDs can be difficult to diagnose on clinical grounds alone. This chapter presents an approach for the

Table 63-1 Clinical Classification of Interstitial Lung Diseases (ILDs)

IDIOPATHIC FIBROTIC DISORDERS

Acute interstitial pneumonitis (Hamman-Rich syndrome)
Idiopathic pulmonary fibrosis/usual interstitial pneumonia
Familial pulmonary fibrosis
Respiratory bronchiolitis/desquamative interstitial pneumonitis
Cryptogenic organizing pneumonia
Nonspecific interstitial pneumonia
Lymphocytic interstitial pneumonia (Sjögren syndrome, connective tissue disease, AIDS, Hashimoto thyroiditis)
Autoimmune pulmonary fibrosis (inflammatory bowel disease, primary biliary cirrhosis, idiopathic thrombocytopenic purpura, autoimmune hemolytic anemia)

CONNECTIVE TISSUE DISEASE-ASSOCIATED ILDs

Scleroderma
Polymyositis-dermatomyositis
Systemic lupus erythematosus
Rheumatoid arthritis
Mixed connective tissue disease
Primary Sjögren syndrome
Ankylosing spondylitis
Behçet syndrome

TREATMENT-RELATED OR DRUG-INDUCED ILDs

Antibiotics (nitrofurantoin, sulfasalazine, cephalosporins, minocycline, ethambutol)
Antiarrhythmics (amiodarone, angiotensin-converting enzyme inhibitors, tocainide, β -blocking agents)
Anti-inflammatories (gold, penicillamine, nonsteroidal anti-inflammatory agents, leflunomide, TNF- α inhibitors)
Anticonvulsants (phenytoin, fluoxetine, carbamazepine, antidepressants)
Chemotherapeutic agents (mitomycin C, bleomycin, alkylating agents, busulfan, cyclophosphamide, chlorambucil, melphalan, methotrexate, azathioprine, cytosine arabinoside, BCNU [carmustine], CCNU [lomustine] procarbazine, nilutamide, interferon- α , paclitaxel, interleukin-2)
L-tryptophan
Dopaminergic drugs (bromocriptine)
Radiation
Oxygen toxicity
Paraquat
Bacille Calmette-Guérin
Narcotics

HEREDITARY ILDs

Gaucher disease
Niemann-Pick disease
Hermansky-Pudlak syndrome
Neurofibromatosis

OTHER CAUSES OF ILD

Aspiration
Exogenous lipid pneumonia
Lymphangitic carcinomatosis
Adenocarcinoma with lepidic pattern or mucinous type (formerly called bronchoalveolar carcinoma)
Pulmonary lymphoma

PRIMARY (UNCLASSIFIED) ILDs

Sarcoidosis
Pulmonary Langerhans cell histiocytosis (eosinophilic granuloma)
Amyloidosis
Pulmonary vasculitis
Lymphangioleiomyomatosis (with or without tuberous sclerosis)
Acute respiratory distress syndrome
AIDS
Bone marrow transplantation
Postinfection
Eosinophilic pneumonia
Alveolar proteinosis
Diffuse alveolar hemorrhage syndromes
Pulmonary veno-occlusive disease
Alveolar microlithiasis
Metastatic calcification

OCCUPATIONAL AND ENVIRONMENTAL ILDs

Inorganic

Silicosis asbestosis
Hard-metal pneumoconiosis
Coal workers' pneumoconiosis
Berylliosis
Talc pneumoconiosis
Siderosis (arc welder)
Stannosis (tin)

Organic (hypersensitivity pneumonitis)

Bird breeder's lung
Farmer's lung

(For complete listing, see Chapter 64)

Table 63-2 Histologic Patterns in Interstitial Lung Diseases and Their Disease Associations

Histologic Patterns	Clinical Associations
Usual interstitial pneumonia	Idiopathic pulmonary fibrosis; connective tissue diseases (uncommon); asbestosis; hypersensitivity pneumonitis; chronic aspiration pneumonia; chronic radiation pneumonitis; Hermansky-Pudlak syndrome; neurofibromatosis
Nonspecific interstitial pneumonia	Idiopathic; connective tissue diseases; drugs; hypersensitivity pneumonitis; resolving diffuse alveolar damage; AIDS; infections
Diffuse alveolar damage	Acute interstitial pneumonia (Hamman-Rich syndrome); acute respiratory distress syndrome; drugs (cytotoxic agents, heroin, cocaine, paraquat, ethchlorvynol, aspirin); toxic gas inhalation; radiation therapy; oxygen toxicity; connective tissue disease; infections (<i>Legionella</i> , <i>Mycoplasma</i> , viral)
Organizing pneumonia	Cryptogenic organizing pneumonia; organizing stage of diffuse alveolar damage; organizing infections (e.g., influenza) as part of diffuse alveolar hemorrhage; drugs (amiodarone, cocaine); infections; connective tissue diseases; hypersensitivity pneumonitis; eosinophilic pneumonia; granulomatosis with polyangiitis (Wegener)
Desquamative interstitial pneumonia/respiratory bronchiolitis	Cigarette smoking; idiopathic; connective tissue diseases; primary pulmonary Langerhans cell histiocytosis; asbestosis; hard-metal pneumoconiosis (cobalt); Gaucher disease; Niemann-Pick disease; Hermansky-Pudlak syndrome; drugs (nitrofurantoin, amiodarone)
Lymphocytic interstitial pneumonia	Idiopathic; hypogammaglobulinemia; autoimmune diseases, including Hashimoto thyroiditis, lupus erythematosus, primary biliary cirrhosis, Sjögren syndrome, myasthenia gravis, chronic active hepatitis; AIDS; allogeneic bone marrow transplantation
Eosinophilic pneumonia	Idiopathic acute and chronic; tropical filarial eosinophilia; parasitic infections; allergic bronchopulmonary aspergillosis; eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome); hypereosinophilic syndrome; AIDS
Alveolar proteinosis	Pulmonary alveolar proteinosis; acute silicosis; aluminum dust; AIDS; myeloproliferative disorder
Diffuse alveolar hemorrhage (with capillaritis)	Granulomatosis with polyangiitis (Wegener); microscopic polyangiitis; systemic lupus erythematosus; polymyositis; scleroderma; rheumatoid arthritis; mixed connective tissue disease; lung transplantation; drugs (retinoic acid, propylthiouracil, dilantin); Behçet disease; cryoglobulinemia; Henoch-Schönlein purpura; pauci-immune glomerulonephritis; immune complex glomerulonephritis
Amyloid deposition	Primary amyloidosis; multiple myeloma; lymphocytic interstitial pneumonia, lymphoma
Granuloma	Sarcoidosis; hypersensitivity pneumonitis; pulmonary Langerhans cell histiocytosis; intravenous talcosis; berylliosis; lymphocytic interstitial pneumonia; infections

evaluation of these patients with emphasis on *idiopathic interstitial pneumonias* (IIPs). An alternative method of histopathologic classification depends on the pattern of injury found on lung biopsy. As seen in Table 63-2, dissimilar clinical entities may result in similar histologic appearances.

The number of ILDs is daunting, but they are linked by many common features: clinical presentation, radiographic appearance, physiologic abnormalities, and, in some instances, histologic findings. Nevertheless, a specific diagnosis can be made in many patients from the results of a careful history and certain laboratory tests. Bronchoscopy with *bronchoalveolar lavage* (BAL) and, often, transbronchial biopsy are useful in the diagnosis of some causes of interstitial infiltration. Thoracoscopic or open-lung biopsy is required for a definitive diagnosis of the remaining cases. Further information about many of the specific members of the interstitial disease family in this section is found in Chapters 65 through 68. Additional discussion of other causes of ILD is found elsewhere in the book: the pneumoconioses in Chapter 73, hypersensitivity pneumonitis in Chapter 64, and drug-induced pulmonary disease in Chapter 71.

CLINICAL, RADIOLOGIC, AND PHYSIOLOGIC FEATURES OF INTERSTITIAL LUNG DISEASES

The hallmarks of an ILD are progressive dyspnea and cough, an abnormal chest radiograph, and impaired pul-

monary function tests.³ However, 5% to 10% of symptomatic patients eventually diagnosed as having ILD have normal chest radiographs at the time of presentation. There are also dyspneic patients with or without abnormal chest radiographs in whom routine pulmonary function tests (flows, volumes, and diffusing capacity) are normal. Some patients with ILD (e.g., sarcoidosis) on chest imaging may have no associated symptoms or pulmonary function abnormalities. Exercise testing, which stresses the cardiopulmonary system and measures gas exchange, may unmask abnormalities in these situations. Furthermore, *high-resolution computed tomography* (HRCT) scans and BAL can detect abnormalities in the presence of normal radiographs and physiologic tests in patients at high risk for development of ILD, such as those with connective tissue disease, asbestos exposure, or hypersensitivity pneumonitis, and those taking drugs known to injure the lung.

PAST HISTORY

ILD developing in a patient with an established connective tissue disease is obvious; however, there are patients in whom the lung disease precedes the more typical manifestations of the associated systemic disease by months to several years.

Occupational and Environmental History

The occupational and environmental history is of obvious importance. It should be thorough and detailed because a long latency period may occasionally exist between exposure and the appearance of clinical impairment and

disability. The exposure may have been of short duration but high intensity. Hypersensitivity pneumonitis, which can manifest either as recurrent acute or subacute pneumonitis or as an insidious form with slowly progressive dyspnea, must be excluded (see Chapter 64). A growing list of occupational and environmental antigens can cause granulomatous pneumonitis.

Drug History

A review of the medications used in the recent and distant past is important. Uncommonly, lung disease may appear weeks to years after the drug has been discontinued (see Chapter 71). Aspiration (often silent) of gastric contents because of *gastroesophageal reflux* (GER) can lead to the insidious development of ILD,⁴⁻⁶ as can the nocturnal use of oily nose drops or use of mineral oil as a laxative.⁷

Smoking History

Determining any history of tobacco use is important. More than 90% of patients with *pulmonary Langerhans cell histiocytosis* (PLCH) of the lung are smokers at the time of diagnosis; this is also true for respiratory bronchiolitis.⁸ Of patients with Goodpasture syndrome who smoked, 100% had diffuse alveolar hemorrhage, whereas only 20% of a nonsmoking group had pulmonary disease in addition to the renal involvement.⁹ Tobacco use also appears to enhance the development of interstitial fibrosis in an asbestos-exposed population. The risk of asbestosis in exposed smokers was 13 times that in a nonsmoking asbestos-exposed cohort. Most patients with IPF have a history of tobacco abuse. Conversely, hypersensitivity pneumonitis infrequently appears in the active smoker. Also, the incidence of sarcoidosis is lower in smokers.

Family History

Familial associations (with an autosomal dominant pattern) have been identified in cases of IPF, sarcoidosis, tuberous sclerosis, and neurofibromatosis; Niemann-Pick disease, Gaucher disease, and Hermansky-Pudlak syndrome are inherited in an autosomal recessive fashion⁶⁻⁸ (see “[Familial Pulmonary Fibrosis](#)” later).

GENDER

There are ILDs with a sex predilection. Lymphangioleiomyomatosis arises almost exclusively in women. In addition, many connective tissue diseases more commonly affect women. Occupational causes are more likely in men. However, transmission of inorganic dust, either from clothes or by living in the vicinity of a manufacturing or mining facility, has resulted in asbestosis and berylliosis in women, children, and men not employed in the industry.

SYMPTOMS

Progressive *dyspnea* is usually the most common symptom, but cough can be prominent, particularly in those patients with lymphangitic carcinomatosis in which the bronchial lymphatic channels are infiltrated.

Cough is a prominent symptom in ILDs, especially those that affect small airways or are bronchiolocentric in location, such as sarcoidosis, respiratory bronchiolitis, organiz-

ing pneumonia, PLCH, and hypersensitivity pneumonitis. In some ILDs such as IPF, cough can be debilitating.

Wheezing, an unusual symptom in ILD, has been reported with lymphangitic carcinomatosis, chronic eosinophilic pneumonia, respiratory bronchiolitis, and hypersensitivity pneumonitis.

Substernal chest pain, an unusual complaint for most ILDs, is frequent in sarcoidosis. *Pleuritic-type chest pain* may accompany connective tissue and drug-related ILDs. The sudden appearance of *chest pain* due to a pneumothorax can be the presenting manifestation or complicate preexisting PLCH, lymphangioleiomyomatosis, tuberous sclerosis, or neurofibromatosis.

Hemoptysis is typical for the diffuse alveolar hemorrhage syndromes, lymphangioleiomyomatosis, pulmonary veno-occlusive disease, and long-standing mitral valve disease. However, alveolar hemorrhage may be present without hemoptysis. Hemoptysis in a patient with an established ILD raises the possibility of a complicating malignancy.

Symptoms in patients with ILD are present for months to years and progress at varying rates. Several interstitial reactions are acute (days to several weeks). These are often confused with atypical pneumonias because they cause diffuse radiographic opacities and may be associated with fever. Included are *acute interstitial pneumonia* (AIP; Hamman-Rich syndrome), acute eosinophilic pneumonia, some cases of hypersensitivity pneumonitis, occasionally drug-related ILDs, some cases of organizing pneumonia, the diffuse alveolar hemorrhage syndromes, and the acute immunologic pneumonias seen with connective tissue diseases.

PHYSICAL FINDINGS

The most typical physical finding is bibasilar inspiratory crackles. Crackles are less likely in the granulomatous diseases. Bilateral inspiratory crackles may also be present in a symptomatic patient with a negative chest radiograph. Clubbing of the digits, which in most cases indicates advanced fibrotic disease, is a common finding in patients with the idiopathic or familial forms of pulmonary fibrosis. However, the appearance of digital clubbing in a patient with an established case of ILD could indicate an underlying bronchogenic carcinoma. With advanced fibrosis causing chronic hypoxemia, clinical signs of pulmonary hypertension and cor pulmonale appear. Attention to potential extrapulmonary physical findings or other manifestations may reveal a specific diagnosis ([Table 63-3](#)).

RADIOLOGIC FEATURES

Although standard chest radiography is not as sensitive for detection of ILD as the HRCT scan, it is the logical starting point and the initial way of identifying and defining disease.

Chest Radiography

Ziskind and coworkers¹⁰ classified diffuse lung diseases according to the pattern on chest radiographs—alveolar filling and primarily interstitial patterns (reticular or nodular). Although *computed tomography* (CT) scanning has supplanted the chest radiograph in the assessment of diffuse parenchymal lung diseases, it is still useful to recognize these radiographic patterns.

Table 63-3 Extrapulmonary Physical Findings and Clinical Manifestations in Interstitial Lung Diseases

Finding	Examples
Systemic hypertension	Connective tissue disease; neurofibromatosis; some diffuse alveolar hemorrhage syndromes
Erythema nodosum	Sarcoidosis; connective tissue disease; Behçet syndrome
Maculopapular rash	Drug-induced; amyloidosis; lipoidosis; connective tissue diseases; Gaucher disease
Heliotrope rash	Dermatomyositis
Albinism	Hermansky-Pudlak syndrome
Discoid lupus	Systemic lupus erythematosus
Neurofibroma	Neurofibromatosis
Telangiectasia	Scleroderma
Raynaud phenomenon	Connective tissue disease
Cutaneous vasculitis	Systemic vasculitides; connective tissue disease
Subcutaneous nodules	Neurofibromatosis; rheumatoid arthritis
Calcinosis	Dermatomyositis; scleroderma; amyloidosis
Uveitis	Sarcoidosis; Behçet syndrome; ankylosing spondylitis
Scleritis	Systemic vasculitis; systemic lupus erythematosus; scleroderma; relapsing polychondritis; sarcoidosis
Keratoconjunctivitis sicca	Lymphocytic interstitial pneumonia (Sjögren syndrome)
Salivary gland enlargement	Sarcoidosis, lymphocytic interstitial pneumonia (Sjögren syndrome)
Peripheral lymphadenopathy	Sarcoidosis; lymphangitic carcinomatosis; lymphocytic interstitial pneumonia; lymphoma
Hepatosplenomegaly	Sarcoidosis; pulmonary Langerhans cell histiocytosis; connective tissue disease; amyloidosis; lymphocytic interstitial pneumonia
Pericarditis	Radiation pneumonitis; connective tissue disease; systemic vasculitis
Myositis	Connective tissue disease; drugs (L-tryptophan)
Bone involvement	Pulmonary Langerhans cell histiocytosis; sarcoidosis; Gaucher disease; lymphangitic carcinomatosis
Arthritis	Connective tissue disease; systemic vasculitis; sarcoidosis
Diabetes insipidus	Pulmonary Langerhans cell histiocytosis; sarcoidosis
Glomerulonephritis	Systemic vasculitis; connective tissue disease; Goodpasture syndrome; sarcoidosis
Nephrotic syndrome	Amyloidosis; drug-induced (gold, penicillamine); systemic lupus erythematosus
Renal mass	Lymphangioleiomyomatosis; tuberous sclerosis

Table 63-4 Interstitial Lung Diseases Producing an Alveolar Filling Pattern on Chest Radiograph

Alveolar proteinosis (proteinaceous fluid)
Adenocarcinoma with lepidic pattern or mucinous type (formerly called bronchoalveolar carcinoma) (malignant cells)
Bronchioloalveolar metastases (malignant cells from pancreas, breast)
Pulmonary lymphoma (malignant lymphocytes)
Lymphocytic interstitial pneumonia (lymphoplasmacytic cells)
Alveolar sarcoid (lymphocyte-macrophage alveolitis or confluent granuloma)
Desquamative interstitial pneumonia (macrophages)
Diffuse alveolar hemorrhage (red blood cells; hemosiderin-filled macrophages)
Eosinophilic pneumonia (eosinophils, macrophages; lymphocytes)
Alveolar microlithiasis (calcium-phosphate microliths)
Organizing pneumonia (Masson bodies)
Exogenous lipid pneumonia (lipid-filled macrophages)
Acute hypersensitivity pneumonia (lymphoplasmacytic cells)

Alveolar Filling Pattern. Alveolar filling (Table 63-4) is recognized by a homogeneous opacity that can be diffuse or patchy and is characterized by confluent nodules with ill-defined outer borders, air bronchograms, and obliteration or silhouetting of normal structures such as the diaphragm,

heart, and intrapulmonary blood vessels (Fig. 63-2). Another feature occasionally seen with alveolar filling is the air alveologram, which represents small areas of uninflated lung in an area of incomplete consolidation, manifesting on the chest radiograph (Fig. 63-3) as small lucent areas within areas of increased lung opacity due to consolidation. So-called “acinar rosettes,” also referred to as “acinar nodules” or “air space nodules,” may be seen when alveolar filling is present and represent centrilobular or peribronchial nodules, rather than actual opacification of individual acini. Several have associated hilar adenopathy (e.g., sarcoidosis, pulmonary lymphoma). In patients with alveolar proteinosis, sparing of the lung parenchyma immediately adjacent to the diaphragm is seen. In chronic eosinophilic pneumonia, the pattern has been referred to as the radiographic negative of pulmonary edema because the alveolar opacities are most prominent in the periphery. A similar alveolar pattern has also been reported in some patients with organizing pneumonia (Fig. 63-4).

Interstitial Pattern. Radiographic interstitial opacities become apparent when the interstitial compartment becomes infiltrated and widened by inflammatory cells, excessive collagen, granulomatous inflammation, or smooth muscle proliferation. In other instances, malignant cells or amyloid deposits expand this compartment. These opacities appear as nodules, linear reticular opacities, or a

Figure 63-2 Frontal chest radiograph illustrating an alveolar filling pattern, or air-space consolidation. This homogeneous opacity obscures vascular margins, tends to extend to the pleural surfaces and is often associated with air bronchograms (*arrow*). This patient had pneumococcal pneumonia, but an alveolar filling radiographic pattern can be seen in patients with several interstitial lung diseases (see [Table 63-4](#)). (Courtesy Michael Gotway, MD.)

Figure 63-3 Detailed view of chest radiograph showing alveolar opacities with ill-defined nodules and distal air alveolograms. This patient had adenocarcinoma (formerly called bronchoalveolar) carcinoma, but this pattern can be seen in several interstitial lung diseases (see [Table 63-4](#)).

combination of linear shadows and nodules (“reticulonodular” opacities).

Nodular Pattern. Nodules of varying size characterize granulomatous lung diseases. Miliary nodules accompany infectious granulomas and noninfectious granulomas (e.g., sarcoidosis, PLCH, and hypersensitivity pneumonitis) and some malignant diseases (e.g., melanoma, hypernephroma, and lymphoma) ([Fig. 63-5](#)). However, linear opacities possibly representing an underlying cellular interstitial infiltrate are also visible.

Figure 63-4 Frontal chest radiograph showing subpleural, upper lobe consolidation in a patient with chronic eosinophilic pneumonia (arrows). A similar pattern may be seen in organizing pneumonia. (Courtesy Michael Gotway, MD.)

Figure 63-5 Frontal chest radiograph showing circumscribed small interstitial-appearing “miliary” nodules. A nodule is also present in the right lower lobe. This patient had metastatic malignant melanoma, but this pattern can also be seen in sarcoidosis, pulmonary Langerhans cell histiocytosis, and hypersensitivity pneumonitis.

Linear or Reticular. Linear or reticular interstitial changes are seen in most ILDs ([Fig. 63-6](#)). It is typical for many ILDs (e.g., IPF, the connective tissue diseases, asbestosis, cytotoxic drug-induced disorders) to have the greatest concentration of the reticular opacities in the lower lung zones. The term *radiographic honeycomb lung* refers to a reticular and cystic pattern that correlates with the histologic “honeycombing.” These small cystic structures, which are best seen in the lower and peripheral lung zones, indicate an underlying advanced fibrotic change ([Fig. 63-7](#)).

A criticism of the alveolar-interstitial classification is that a mixed pattern is often found. For example, interstitial fibrosis may eventually be superimposed on a disease

Figure 63-6 Frontal chest radiograph in a patient with idiopathic pulmonary fibrosis. Peripheral basal predominant reticulation is seen consistent with fibrotic lung disease. Note diminished lung volumes. (Courtesy Michael Gotway, MD.)

Figure 63-7 Frontal chest radiograph showing characteristic features of honeycomb lung. A network of 2- to 3-mm cystic spaces is distributed throughout the lung fields. This patient with end-stage idiopathic pulmonary fibrosis also had pulmonary hypertension and was receiving oxygen through a transtracheal catheter.

that was primarily alveolar, such as alveolar proteinosis, diffuse alveolar hemorrhage, eosinophilic pneumonia, or organizing pneumonia. Sarcoidosis, a disease characterized by interstitial granuloma, can be alveolar in appearance due to either coalescence of granulomas with compression of adjacent lung or a lymphocyte-macrophage alveolitis. Dense fibrosis from any fibrotic lung disease can compress adjacent lung, producing homogeneous shadows. The appearance of alveolar opacities during the course of an ILD may represent renewed activity of the primary disease, superimposed infection, or development of adenocarcinoma.^{11,12}

Other Radiographic Features. Several distinctive patterns may accompany the interstitial changes and may point to a diagnosis (Table 63-5). There are a group of interstitial diseases, often granulomatous, in which the radiographic changes are more prominent in the upper lung zones (Fig. 63-8). Some interstitial diseases are bronchiolocentric, resulting in either maintenance or expansion of the lung volume. If an ILD is superimposed on emphysema, the lung volumes are often preserved. The majority of ILDs result in a gradual reduction of the lung volumes. In fact, lower lobe volume loss and traction bronchiectasis are typical for the advanced stages of these diseases.^{11,13} Short horizontal lines at the lung periphery (Kerley B lines), representing thickened interlobular septa, are seen after obstruction of the pulmonary lymphatics (Fig. 63-9). Pneumothorax is often the presenting manifestation of PLCH or lymphangioleiomyomatosis. Diaphragmatic pleural calcification in a patient with interstitial opacities is indicative of asbestos exposure. Pleural thickening and pleural effusion may complicate the course of the connective tissue-associated ILDs. Chronic hypoxemia results in radiographic evidence of pulmonary hypertension.

Computed Tomography

Conventional chest radiographic assessment for ILD may miss up to 10% of cases.¹⁴ Conventional CT, obtained using 8- to 10-mm slices, offers little more for the detection of

Table 63-5 Radiologic Features of Interstitial Lung Diseases

Feature	Diseases
Upper zone—predominant disease	Radiation pneumonitis; neurofibromatosis; chronic sarcoidosis; pulmonary Langerhans cell histiocytosis; silicosis; coal workers' pneumoconiosis; chronic hypersensitivity pneumonitis; chronic eosinophilic pneumonia; ankylosing spondylitis; nodular rheumatoid arthritis; berylliosis; drug-induced (amiodarone, gold, bischloroethyl carmustine nitrosourea [carmustine]); radiation
Increased lung volumes	Lymphangioleiomyomatosis (with or without tuberous sclerosis); chronic sarcoidosis; pulmonary Langerhans cell histiocytosis; neurofibromatosis
Radiologic honeycomb lung	Idiopathic pulmonary fibrosis; connective tissue disease; asbestosis; drug-induced; lymphocytic interstitial pneumonia; chronic aspiration pneumonia; hemosiderosis; Hermansky-Pudlak syndrome
Pneumothorax	Pulmonary Langerhans cell histiocytosis; lymphangioleiomyomatosis (with or without tuberous sclerosis); neurofibromatosis
Kerley B lines	Lymphangitic carcinomatosis; lymphangioleiomyomatosis; left atrial hypertension (mitral valve disease, veno-occlusive disease); lymphoma; amyloidosis
Lymphadenopathy	Sarcoidosis; lymphoma; lymphangitic carcinomatosis; lymphoid interstitial pneumonia; berylliosis; amyloidosis; Gaucher disease
Pleural disease	Lymphangitic carcinomatosis; connective tissue disease; asbestosis (pleural calcification); lymphangioleiomyomatosis (chylous effusion); drug-induced (nitrofurantoin, radiation); sarcoidosis
Eggshell calcification of lymph nodes	Silicosis; sarcoidosis; radiation

radiographic-negative ILD. HRCT, obtained with a section thickness of less than 2 mm, enables better visualization of fine parenchymal detail and therefore the detection of early air space filling or interstitial change (Fig. 63-10). In cases of suspected ILD with negative conventional radiography, it is important to perform HRCT in the prone and supine positions. Dependent lung density can mask interstitial change, and vascular engorgement of the dependent portion of lung mimics septal thickening on supine imaging. Abnormalities that persist on prone imaging are indicative of disease.

In patients with abnormal chest radiographs, the diagnostic accuracy increases with HRCT evaluation. In cases of IPF, peripheral reticular opacities, lower zone subpleural honeycombing, and traction bronchiectasis are seen (Fig. 63-11).^{15,16} In the connective tissue diseases, asbestosis,

and some drug-induced ILD, the results on HRCT, as on chest radiography, are indistinguishable from those of IPF or *nonspecific interstitial pneumonia* (NSIP). In scleroderma, a disease in which the prevalence rate of ILD approaches 100% in autopsy series, HRCT detects disease in 45% to 75% of patients when conventional radiography is negative.^{17,18}

In sarcoidosis, in addition to the hilar and mediastinal adenopathy, nodules deposited along bronchovascular bundles and interlobular septa, air space filling due to the lymphocyte-macrophage alveolitis, and linear densities secondary to fibrotic scarring can be seen (Fig. 63-12). In patients with hypersensitivity pneumonitis, air space-filling centrilobular nodules and linear opacities without adenopathy are present. The HRCT can be normal in symptomatic patients with biopsy-proved hypersensitivity pneumonitis.¹⁹ In patients with PLCH, the combination of centrilobular nodules and cysts, most prominent in the upper lobes and occasionally accompanied by a pneumothorax, is

Figure 63-8 Uncomplicated silicosis. Frontal chest radiograph shows upper and mid lung predominant small nodules. Note that some of these nodules are calcified. (Courtesy Michael Gotway, MD.)

characteristic (Fig. 63-13). In earlier PLCH, coalescence of the nodules produces an air space–filling pattern.

In lymphangioleiomyomatosis, the HRCT is typical, revealing rounded, thin-walled cysts throughout (Fig. 63-14). A pneumothorax or pleural effusion (chylous) may accompany this change. Identical findings are present in lymphangioleiomyomatosis associated with tuberous sclerosis. Lymphangitic carcinomatosis produces a beaded-chain appearance of the interlobular septa that correlates with Kerley B lines seen with conventional radiography. In asbestos-related disease, noncalcified pleural plaques and early ILD are often difficult to detect, and the HRCT is more sensitive than conventional chest radiography.

Figure 63-14 Lymphangioleiomyomatosis. High-resolution CT image shows characteristic thin-walled cysts throughout the parenchyma.

FUNCTIONAL ASSESSMENT

In ILD, there are characteristic alterations of the lungs' mechanical properties and impairment of gas exchange at the alveolar–capillary interface. Assessment of ventilatory function and the mechanical properties of the lungs, as well as gas exchange, particularly during exercise, are vital components of the initial evaluation of patients with suspected ILD. In addition, serial measurements of function enable the physician to determine progression of the disease and the effects of therapeutic intervention.

Ventilatory Function

Ventilatory function tests provide an indirect index of alterations to the impedance to respiration offered by the elastic resistance to distention of the lungs and the frictional resistance to airflow in the tracheobronchial tree. Clinically, alterations of the mechanical properties of the respiratory system are also reflected in the pattern of breathing that is adopted by the patient. These patients tend to breathe rapidly and shallowly because a larger tidal volume would require an inordinate increase in work of breathing to overcome the greatly increased elastic resistance.

Elastic Resistance

ILD is associated with an increase in elastic resistance (or decreased compliance), and this can be seen in a plot of the static transpulmonary pressure (i.e., at points of no flow) at differing decrements of lung volume from *total lung capacity* (TLC) to residual volume. In most patients with ILD, the plot of the volume-pressure relationship of the lungs is characteristically shifted downward and to the right, with a reduced slope (i.e., compliance is low) and a markedly increased coefficient of elastic recoil (maximum elastic recoil pressure, TLC). Conversely, as is demonstrated in Figure 63-15, there is significant variation in the position of the volume-pressure curve in patients with IPF and sarcoidosis,²⁰ and the correlation between alterations of the elastic properties (and lung volume compartments) and the degree of fibrosis present is poor. This is, at least in part, a consequence of the impact of smoking, which appears to

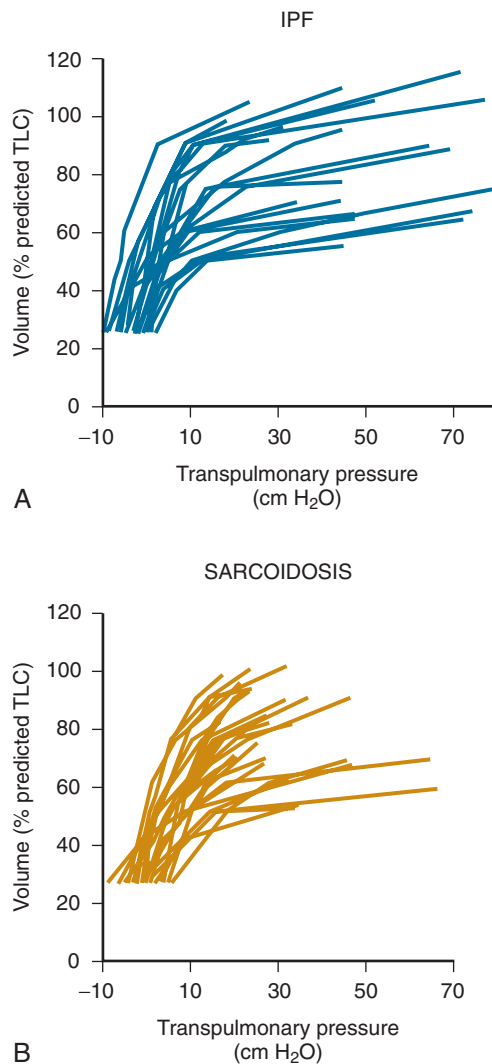

Figure 63-15 Multiple recordings show volume-pressure characteristics in patients with idiopathic pulmonary fibrosis (IPF) (A) and sarcoidosis (B). Note the marked variation of position and shape in both disorders. TLC, total lung capacity. (Redrawn from Hanley ME, King TE Jr, Schwarz MI, et al: The impact of smoking on mechanical properties of the lungs in idiopathic pulmonary fibrosis and sarcoidosis. *Am Rev Respir Dis* 144:1102, 1991.)

differ in the two disorders. In patients with IPF who smoke, the volume-pressure curve is shifted upward and to the left, whereas in patients with sarcoidosis who smoke, it is shifted downward and to the right.²⁰

Measurements of lung volume reflect changes in position of the volume-pressure curve of the lungs. This is because alterations of the elastic recoil of the lung or chest wall disturb the balance between the elastic forces of the lungs, which act in an expiratory direction, and those of the chest wall, which act in an inspiratory direction. In patients with ILD, the TLC, functional residual capacity, and residual volume are generally reduced (Fig. 63-16). A lower than expected TLC (and vital capacity) in association with a normal functional residual capacity and a greater than expected residual volume generally reflects a mixed restrictive and obstructive disorder. However, because maximum effort is necessary to determine the inspiratory capacity and the expiratory reserve volume, a less than maximal inspiration or expiration, either because of weak respiratory muscles or because of poor effort, leads to the same findings. Similar considerations apply to the vital capacity, which is often used as an index of alterations of elastic resistance. In addition, as can be seen in Figure 63-16, a low vital capacity is not specific for restrictive disorders because it is also lower than expected in patients with airflow limitation (because of an increased residual volume).

Flow Resistance

Measurement of lung volume is important when evaluating airflow resistance. This can be assessed directly from the relationship between the rate of airflow and the resistive component of the transpulmonary pressure.

In clinical practice, various indirect measures of flow resistance can be used: the *forced expiratory volume in 1 second* (FEV₁); the mean expiratory flow rate between 25% and 75% of the forced vital capacity (FEF_{25%-75%}); the maximal expiratory flow rate (\dot{V}_{max}) at a particular proportion (such as 75%, 50%, or 25%) of the *forced vital capacity* (FVC) (from a flow-volume curve); the FEV₁/FVC ratio;

Figure 63-16 Bar graphs show total lung capacity (TLC) and its subdivisions in healthy persons (normal) compared with the typical abnormalities found in patients with restrictive disorders, obstructive disorders, and mixed disorders. FRC, functional residual capacity; RV, residual volume; VC, vital capacity. (Redrawn from Cherniack RM: Pulmonary function testing. Philadelphia, 1992, WB Saunders, p 212.)

or the FEV₁-to-vital capacity ratio. Low flow rates or a low FEV₁/FVC ratio (i.e., <70% of predicted) is believed to indicate expiratory airflow limitation. However, like airway resistance, \dot{V}_{\max} values depend on the diameter of the airways, which is influenced by the lung volume. The FEV₁/FVC ratio will be overestimated, and the degree of flow limitation underestimated, in the patient who does not exhale fully because of severe dyspnea or muscular weakness, pain, or poor effort.

Airflow resistance is not generally thought to be increased in ILD. As is seen in Figure 63-17, \dot{V}_{\max} is low in ILD, not because of an increase in flow resistance but rather because of the low lung volumes at which the flow is being measured. In fact, in uncomplicated ILD, \dot{V}_{\max} values are greater than expected at any particular lung volume because the lung elastic recoil pressure, which is the driving pressure for flow in the peripheral airways, is increased.¹⁹ As a corollary, a \dot{V}_{\max} lower than expected at a particular lung volume in a patient who is suffering from a restrictive

disorder indicates an increase of flow resistance in the more peripheral airways. An increase in peripheral airway resistance has been reported in patients with IPF, hypersensitivity pneumonitis, and asbestos exposure.

Gas Exchange

Alterations of gas exchange are readily assessed by analysis of the arterial oxygen pressure (PO₂) and carbon dioxide pressure (PCO₂) and calculation of the alveolar-arterial PO₂ difference ((A-a)PO₂), both at rest and during exercise.

In patients with ILD, arterial blood analysis while at rest usually reveals hypoxemia and an increased (A-a)PO₂, along with hypocapnia. In addition, the diffusing capacity for carbon monoxide (DL_{CO}) is reduced, primarily because of a reduction in the alveolar-capillary surface available for gas exchange. The disturbance of gas exchange generally accompanies abnormalities in ventilatory function,²¹ but gas exchange may be normal at rest in a significant number of patients. Similarly, the resting DL_{CO} may be only slightly reduced in patients who demonstrate a mild restrictive disorder or normal gas exchange while at rest, or both.

The DL_{CO} is generally greater than expected in those cases associated with recent pulmonary hemorrhage because the red blood cells in the pulmonary alveoli take up carbon monoxide readily. Sequential measurements of the DL_{CO} within minutes may aid in the establishment of the diagnosis of alveolar hemorrhage.²² When there is fresh blood in the alveolar spaces, each successive DL_{CO} value will be lower as the hemoglobin in the alveoli becomes saturated with carbon monoxide.

Exercise

In most patients, gas exchange is disturbed during exertion, even in those with normal gas exchange at rest. Assessment of gas exchange during exercise provides the best correlation with the severity of disease²³ and is probably the most important physiologic determination in patients with ILD (see Chapter 26).

In general, patients with the most severe restrictive disease have the poorest exercise tolerance. As is shown in Figure 63-18, ventilation generally rises excessively during exercise and may approach the ventilatory ceiling. Characteristically, the respiratory frequency rises inordinately with increasing exercise loads because of the increased work that would be required to overcome the elastic resistance of the lungs if the tidal volume were to increase.

The excessive ventilation is frequently preferentially distributed to areas of lung that have normal compliance but diminished perfusion (i.e., high ventilation-perfusion ratio); as a result, unlike the normal response, the calculated dead space (V_D) and the ratio of dead space to tidal volume (V_D/V_T) rise in association with rapid, shallow breathing. The increase in cardiac output with exercise and the rapid transit of blood through the pulmonary capillaries along with its redistribution in the lungs lead to a greater maldistribution of ventilation-perfusion ratios. This results in a rise in (A-a)PO₂ and a fall in arterial PO₂ (Fig. 63-19). Except for heavy exercise, when the transit through the circulation is exceptionally rapid, it is unlikely that a reduced ability of oxygen to diffuse across a thickened alveolar-capillary membrane plays a significant role in the hypoxemia.

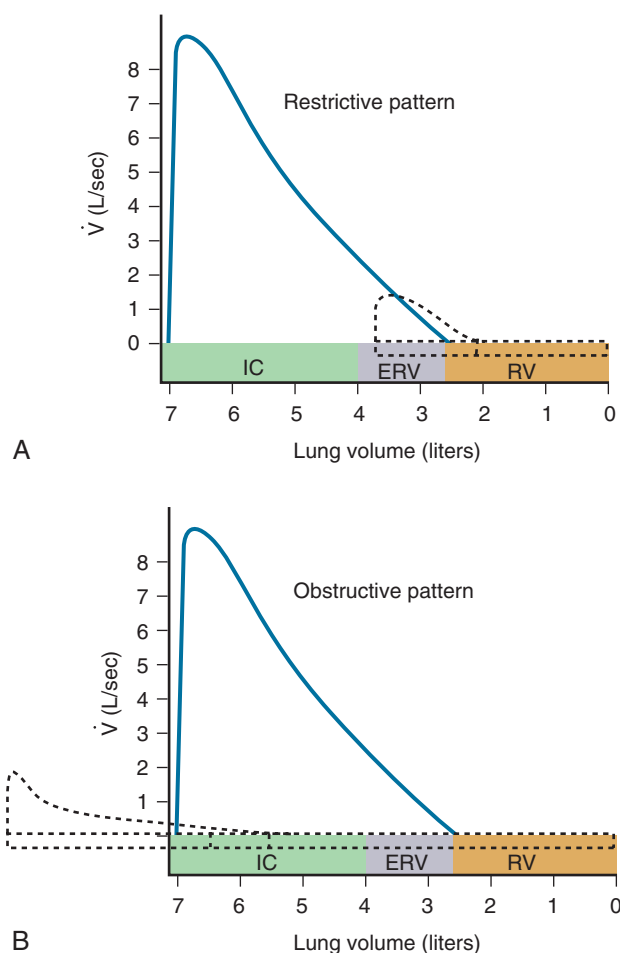

Figure 63-17 Schematic flow-volume curves in a healthy person (solid line) are compared with those in patients (dotted lines) with a restrictive disorder (A) and with an obstructive disorder (B). Lung volume is reduced in the restrictive disorder, and maximum expiratory flow rates are low because they are achieved at low lung volumes. Flow rates are higher than expected at low lung volumes because the driving pressure (lung elastic recoil) is increased. ERV, expiratory residual volume; IC, inspiratory capacity; RV, residual volume; \dot{V} , flow. (Redrawn from Cherniack RM: Pulmonary function testing. Philadelphia, 1992, WB Saunders, p 218.)

LABORATORY FINDINGS

Table 63-6 summarizes the results of laboratory tests that suggest or support the diagnosis of a specific ILD.

BRONCHOALVEOLAR LAVAGE

BAL is a technique employed to sample the distal airways via the instillation of sterile saline through a wedged fiberoptic bronchoscope. After aspiration, the contents, which are thought to represent the cellular, immunologic, and biochemical milieu of the alveolar structures, can be analyzed. The results of BAL for the evaluation of ILD have been difficult to interpret because of the lack of standardized techniques for both the performance of the procedure and the subsequent analysis of the data.²⁴⁻²⁶ Furthermore, in some of the earlier studies, correlative data between BAL and lung biopsies were not obtained. Often, the treatment or smoking status of the patient was not considered. A multicenter publication has set forth the methods of performing

Figure 63-19 The changes in arterial PO_2 (circles), alveolar-arterial PO_2 difference ($(A-a)PO_2$, squares), and arterial carbon dioxide pressure (PCO_2 , triangles) during increasing exercise workloads expressed as the percentage of predicted maximum oxygen uptake ($\dot{V}O_2$) in a healthy person and a patient with idiopathic pulmonary fibrosis. Testing was performed at an altitude of 5280 feet. (Redrawn from Cherniack RM: Pulmonary function testing. Philadelphia, 1992, WB Saunders, p 249.)

and analyzing the results of BAL.²⁷ This study involved a large cohort of normal subjects of varying age and race who were compared with patients with documented ILD. Smoking affects the BAL results of both normal subjects and patients by amplifying the macrophage and eosinophil populations.²⁷

BAL is a useful investigative tool in many ILDs. Cytologic analysis of BAL specimens can be diagnostic for lymphangitic carcinomatosis, adenocarcinoma, and pulmonary lymphoma. If the eosinophil level exceeds 40% (normal, <2%), eosinophilic pneumonia is usually the cause of the diffuse pulmonary infiltration. BAL eosinophilia of a lesser degree may be found with some connective tissue diseases, IPF, or organizing pneumonia.

The finding of periodic acid-Schiff-positive lipoproteinaceous bodies in the BAL was originally thought to be diagnostic for pulmonary alveolar proteinosis but has proved to be nonspecific. In cases of diffuse alveolar hemorrhage, red blood cells and hemosiderin-laden macrophages dominate the lavage specimen. Sequential BAL samples show an increase in red cells and in its bloody appearance (see Fig. 67-3).

BAL lymphocytosis (>35% lymphocytes) predominates in some diseases. Sarcoidosis and hypersensitivity pneumonitis are most common. Others include *lymphocytic interstitial pneumonia* (LIP), pulmonary lymphoma, berylliosis, and some drug-induced ILDs. Smaller but increased percentages of lymphocytes (normal range, 10%–15%) can be seen with these entities in addition to a number of other ILDs, including IPF, organizing pneumonia, connective tissue diseases, and some pneumoconioses.²⁸ In patients with suspected asbestos-related disease, one or more asbestos bodies per high-powered field in the BAL specimen indicate significant exposure, although this does not establish the diagnosis of asbestosis. Because of the vertical gradient of asbestos bodies recovered in the lungs of patients with asbestosis, if

Table 63-6 Laboratory Findings in Interstitial Lung Diseases

Finding	Diseases
Leukopenia	Sarcoidosis; connective tissue disease; lymphoma; drug-induced
Leukocytosis	Systemic vasculitis; hypersensitivity pneumonitis; lymphoma
Eosinophilia	Eosinophilic pneumonias; sarcoidosis; systemic vasculitis; drug-induced (sulfa, nitrofurantoin, methotrexate)
Thrombocytopenia	Sarcoidosis; connective tissue disease; drug-induced; Gaucher disease; idiopathic pulmonary fibrosis
Hemolytic anemia	Connective tissue disease; sarcoidosis; lymphoma; drug-induced; idiopathic pulmonary fibrosis
Normocytic anemia	Diffuse alveolar hemorrhage syndromes; connective tissue disease; lymphangitic carcinomatosis
Urinary sediment abnormalities	Connective tissue disease; systemic vasculitis; drug-induced
Hypogammaglobulinemia	Lymphocytic interstitial pneumonia; granulomatous lymphocytic interstitial lung disease
Hypergammaglobulinemia	Connective tissue disease; sarcoidosis; systemic vasculitis; idiopathic pulmonary fibrosis; asbestosis; silicosis; lymphocytic interstitial pneumonia; lymphoma
Serum autoantibodies	Connective tissue disease; systemic vasculitis; sarcoidosis; idiopathic pulmonary fibrosis; silicosis; asbestosis; lymphocytic interstitial pneumonia
Serum immune complexes	Idiopathic pulmonary fibrosis; lymphocytic interstitial pneumonia; systemic vasculitis; connective tissue disease; pulmonary Langerhans cell histiocytosis
Serum angiotensin-converting enzyme	Sarcoidosis; hypersensitivity pneumonitis; silicosis; acute respiratory distress syndrome; Gaucher disease
Antibasement membrane antibody	Goodpasture syndrome
Antineutrophil cytoplasmic antibody	Systemic vasculitis

lavage is used to document previous asbestos exposure, samples should be obtained from a basal segment of one of the lower lobes. A diagnosis of berylliosis is confirmed when lavaged lymphocytes undergo proliferation after exposure to beryllium *in vitro*.

In the BAL recovered from patients with PLCH, all inflammatory cells are increased even though their percentages remain unchanged. Electron microscopy demonstrates increased numbers of Langerhans cells. This monocyte, which is thought to be central in the pathogenesis, has a typical pentilaminar body (Birbeck granule) in the cytoplasm, as revealed by electron microscopy. Langerin and CD1a are specific diagnostic markers for Langerhans cells.²⁹ Langerhans cells have been described in other fibrotic lung diseases, but not in numbers equivalent to those of PLCH.³⁰

Other applications of BAL include assessment of disease status and the prediction of therapeutic responsiveness. For example, in both the connective tissue diseases and IPF, BAL lymphocytosis is associated with a cellular histology (as opposed to fibrosis) and an improved response to treatment. Furthermore, the overall survival rate in these patients is increased. Conversely, the combination of lavage neutrophilia and eosinophilia without lymphocytosis often portends progressive unresponsive disease. In sarcoidosis, a disease characterized by increases in the number of T-helper (CD4⁺) lymphocytes in the lung, it has been suggested that clinical deterioration may be expected if the BAL lymphocyte level exceeds 28%; however, more recent data indicate that the level of BAL lymphocytes has no value in predicting the clinical outcome in sarcoidosis.

Another role for BAL is in the assessment of potential ILD in populations at risk. For example, in patients with scleroderma and rheumatoid arthritis in whom clinical, radiologic, and physiologic evidence of ILD is lacking, BAL studies have revealed increases in inflammatory cell populations.

HISTOLOGIC DIAGNOSIS

The final step in the evaluation of a patient with ILD is to decide whether tissue is necessary for diagnosis. As previously noted, the diagnosis of connective tissue, occupational, or drug-related ILD is often obvious after a careful history has been taken. In cases of idiopathic and primary ILD (see Table 63-1), the diagnosis may not be as obvious, although clinical, laboratory, and radiologic findings are often suggestive. Furthermore, the diagnosis of IPF, a commonly encountered ILD, in many cases can be established only by lung biopsy.

Transbronchial Biopsy

As a matter of practicality, transbronchial biopsy can be performed during the bronchoscopy for BAL. Transbronchial biopsy is relatively safe and is often diagnostic of sarcoidosis, diffuse malignancy, alveolar proteinosis, or eosinophilic pneumonia. Other entities are less frequently confirmed by this procedure. A transbronchial biopsy interpretation, which describes only inflammation, fibrosis, or both, is not evidence for IPF or any other entity listed in Table 63-1. Furthermore, even in clinically confirmed cases of connective tissue or drug-induced ILD, several different histologic patterns may evolve (see Table 63-2), and surgical lung biopsy is often undertaken to predict prognosis and therapeutic responsiveness, particularly if BAL and HRCT are inconclusive.

Surgical Lung Biopsy

If the transbronchial biopsy, clinical, and BAL data are inconclusive and the patient is not at high risk, a video thorascopic or open-lung biopsy should be performed. Moreover, there is a poor correlation between the results of transbronchial and open-lung biopsies unless the transbronchial biopsy yields a specific diagnosis. Therefore, when the transbronchial biopsy is inconclusive and a definitive

diagnosis is required, open or thoracoscopic lung biopsy is indicated.³¹

DIAGNOSIS AND MANAGEMENT OF IDIOPATHIC INTERSTITIAL PNEUMONIAS

IIPs represent a heterogeneous group of diffuse parenchymal lung diseases characterized by varying patterns of inflammation and fibrosis.^{32,33} This group of lung diseases represents a subset of ILDs and comprises seven clinical-radiologic-pathologic entities that are sufficiently different from one another to be designated as separate diseases.³² The classification, diagnosis, understanding of the pathogenic mechanisms, and management of IIPs continue to evolve.^{34,35} As a group, they can be distinguished from other forms of ILD by clinical methods including history, physical examination, chest radiologic and laboratory studies, and pathology. It is crucial for clinicians to be aware that the

histologic pattern underlying these IIPs can be encountered in subjects with known causes for their lung disease (e.g., connective tissue diseases, smoking, drugs). Thus, *usual interstitial pneumonia* (UIP) can be seen not only in patients with IPF but also in patients with rheumatoid arthritis as a form of rheumatoid arthritis-associated ILD.^{33,36} In addition, the interstitial pneumonia patterns are associated with varying degrees of specificity with respect to etiology. For example, *respiratory bronchiolitis-associated ILD* (RB-ILD) in most patients is caused by smoking, whereas organizing pneumonia can be associated with a broad spectrum of causes including infections, aspiration, drug reactions, connective tissue disorders, eosinophilic lung disease, and many others.^{31,37-41} Tables 63-7 and 63-8 provide an overview of the key clinical and pathologic features of the IIPs.

IDIOPATHIC PULMONARY FIBROSIS

IPF is the most common form of IIP and accounts for 25% to 30% of ILDs.^{2,42-44} IPF is a well-defined clinical entity with

Table 63-7 Contrasting Pathologic Features of Idiopathic Interstitial Pneumonias

Features	UIP	DIP	RB-ILD	AIP	NSIP	COP
Temporal appearance (age of lesion)	Variegated	Uniform	Uniform	Uniform	Uniform	Uniform
Interstitial inflammation	Scant	Scant	Scant	Scant	Usually prominent	Usually moderate
Fibrosis/honeycombing	Patchy	Variable, diffuse, moderate	Variable, focal, mild	Typically no, but may evolve to fibrosis	Variable, diffuse	No
Fibroblast proliferation	Fibroblast foci prominent	No	No	Diffuse	Occasional, diffuse, or rare fibroblast foci	Within airways and air spaces (Masson bodies)
Honeycomb change	Yes	No	No	No	Rare	No
Intra-alveolar macrophage accumulation	Occasional, focal (smokers)	Yes, diffuse	Peribronchiolar	No	Occasional, patchy	Foamy macrophages common
Hyaline membranes	No	No	No	Occasional, focal	No	No

characteristic clinical, radiographic, physiologic, and pathologic manifestations but is also a diagnosis of exclusion (i.e., UIP of unknown cause).^{16,45} The exact prevalence of this condition is unknown. In a recent study using narrow case-finding criteria, the prevalence ranged from 0.8 to 65/100,000 individuals; comparable figures for incidence were 0.4 to 27/100,000 persons.⁴³ Extrapolating these rates to the overall U.S. population, prevalence was estimated to be 14/100,000 (incidence, 7/100,000). Both the prevalence and the incidence of IPF increase markedly with age.⁴³

Clinical Features

IPF is a disease of middle age, usually seen in patients between 50 and 70 years of age. Patients with familial pulmonary fibrosis tend to present at a younger age; otherwise, it is quite uncommon for a patient to present before the age of 40.⁴⁶⁻⁴⁸ The typical patient presents with the insidious onset of exertional breathlessness and a nonproductive cough. Constitutional symptoms are uncommon, but weight loss, fever, fatigue, myalgias, or arthralgia is occasionally present. Although patients may present with only a nonproductive cough, all patients experience dyspnea with exertion as the disease progresses. Most patients have these symptoms for months to years before definitive evaluation, usually around 12 to 18 months.

The physical examination is rarely normal. Most patients have bibasilar late inspiratory fine crackles (Velcro crackles) on chest examination. Clubbing of the fingers is seen in 40% to 75% of patients and is a late finding in the disease course. Cardiac examination is usually normal except in the middle or late stages of the disease, when findings of pulmonary hypertension (e.g., augmented P2, right-sided lift, tricuspid regurgitation, and S3 gallop) and cor pulmonale may become evident. Similarly, cyanosis is a late manifestation indicating advanced disease. Spontaneous pneumothorax or pneumomediastinum is rare.

Blood and Serologic Studies

An elevated erythrocyte sedimentation rate, low-level antinuclear antibodies titer positivity (≥ 40 and $< 1:320$), and elevated rheumatoid factor (> 60 IU/mL) have been identified in some of these patients.⁴⁹ Hemoglobin level along with leukocyte and differential counts are usually normal.

Chest Imaging Studies

Chest Radiography. The typical finding in patients with IPF is peripheral reticular opacities with a netlike appearance of linear or curvilinear densities, with predominance at the lung bases (Fig. 63-20). A coarse reticular pattern or multiple cystic or honeycombed areas (i.e., coarse reticular pattern with translucencies measuring 0.3 to 1 cm in diameter) are radiographic findings that correlate with advanced disease and poor prognosis (see Figs. 63-6 and 63-7). Chest radiographic evidence of reduced lung volumes is usually present unless there is associated obstructive airway disease, as can be seen in smokers.

Pleural abnormalities are uncommon in IPF; their presence should suggest another diagnosis, such as collagen vascular disease (especially rheumatoid arthritis or systemic lupus erythematosus), mitral valve disease, conges-

tive heart failure, asbestosis, infection, drug-induced lung disease, or lymphangitic carcinomatosis (see Table 63-5).

Computed Tomography Scan. CT plays a major role in the evaluation of pulmonary parenchymal diseases, especially IPF.^{16,50,51} HRCT is useful in the differentiation of IPF from other ILDs, the determination of the extent and severity of disease activity, and, most importantly, the detection of disease, especially in patients with normal or minimal change on chest radiography. HRCT findings in IPF include a marked peripheral (subpleural) distribution of the interstitial opacities. The involvement is patchy, with areas of reticulation intermingled with areas of normal tissue, often associated with cystic spaces 2 to 4 mm in diameter (see Fig. 63-11). Early disease appears as patchy, predominantly peripheral, subpleural reticular opacities (eFig. 63-1) and minor degrees of honeycomb change. In more advanced disease, a more diffuse reticular pattern in the lower lung zones with thickened interlobular septa and intralobular lines progresses to traction bronchiectasis and subpleural fibrosis (eFig. 63-2).^{50,51} The predominantly basal nature of these abnormalities is often readily appreciated with coronal imaging (eFig. 63-3).

One of the key findings indicating the diagnosis of IPF is the presence of honeycomb cysts in a basilar subpleural distribution (eFig. 63-4). Honeycomb changes appear on the HRCT scan as variably sized cystic spaces that share walls and frequently stack on one another in several layers.^{50,51} Ground-glass opacities are common but of mild severity and characteristically much less extensive than the reticular pattern. Architectural distortion, which reflects lung fibrosis, is often prominent.

Combined lower lobe pulmonary fibrosis and upper lobe emphysema has been recently described as a new CT-defined syndrome (eFig. 63-5, Video 63-1) (Fig. 63-21).^{52,53} Smoking appears to be the predominant risk factor for this disorder. Patients with this entity are primarily males with a mean age of 65 years who have relatively preserved lung volumes but marked reductions in DL_{CO} on pulmonary function testing. Limited data suggest that these patients with IPF and coexisting emphysema are more likely to require long-term oxygen therapy, to develop pulmonary hypertension, and to have a worse outcome than those without emphysema.^{52,53}

HRCT Correlation with Physiologic Data in ILD. Identification of a relationship between pulmonary function testing and HRCT findings remains incomplete. FVC, DL_{CO}, arterial PO₂ measured at peak exercise, and oxygen desaturation during exercise are the physiologic parameters that best correlate with the global extent of disease on HRCT.^{21,54} In one study, DL_{CO} was the physiologic characteristic most highly correlated with HRCT findings.⁴¹ Serial HRCT scanning showed that the changes over time in the total extent of the disease were similar to those changes observed in DL_{CO} and FVC.⁵⁵

Ability of HRCT Scanning to Diagnose ILD. HRCT plays an important role but has not replaced lung biopsy in the diagnosis and assessment of most ILDs. In the case of IPF, connective tissue diseases (particularly scleroderma) and asbestosis may cause a similar HRCT appearance (except

Figure 63-20 Serial chest radiographs from a patient with idiopathic pulmonary fibrosis. **A**, The frontal chest radiograph was obtained at the time of onset of breathlessness with exercise and mild cough. The chest appears normal. **B**, The follow-up film reveals progressive loss of lung volume and bibasilar, predominantly reticular opacities. The patient had stopped regular exercise because of breathlessness with exertion. **C**, Progressive changes are evident, with severe loss of lung volume. Predominantly in the lower lung zone are seen diffuse, bilateral, coarse reticular opacities typical of the radiographic appearance of the middle to late stage of pulmonary fibrosis. **D**, Continued disease progression is evident, with honeycombing and pulmonary hypertension. Open-lung biopsy revealed usual interstitial pneumonia with extensive fibrosis and histologic honeycombing. Treatment with corticosteroids and cyclophosphamide (Cytoxan) was started, but the patient experienced a progressive decline in functional status and died 6 months after lung transplantation.

for the presence of parenchymal bands of fibrosis and pleural plaques seen in patients with asbestosis).⁵⁶ Patients with chronic hypersensitivity pneumonitis can have similar reticular opacity or honeycombing, but often accompanied by a mosaic pattern, centrilobular nodules, and lack the bibasilar predominance seen in IPF (eFig. 63-6).^{57,58}

Studies evaluating the ability of HRCT scanning to diagnose IPF accurately have found that HRCT significantly increases the level of diagnostic confidence. In general, the sensitivity for a confident diagnosis is low ($\approx 48\%$) but the specificity is high ($\approx 95\%$).⁵⁹⁻⁶³ The accuracy of a confident diagnosis of IPF made on HRCT by a trained observer appears to be about 90%.^{57,64-66} Less experienced observers

are substantially less accurate than experienced observers.⁶⁴ An HRCT pattern highly suggestive of the diagnosis of IPF is associated with a poor prognosis.⁶⁷ Of those with a histopathologic diagnosis of UIP, those with basilar honeycombing have a worse survival than those without honeycombing.^{68,69} In a multivariate analysis of a large multicenter trial, it was found that extent of reticulation and honeycombing on HRCT is an important independent predictor of mortality in patients with IPF.⁵⁵

Other Imaging Techniques

Gallium Scanning. Lung scanning with radioactive gallium (^{67}Ga) is a noninvasive test for staging the

Figure 63-21 Combined pulmonary fibrosis and emphysema. CT images from a 69-year-old woman with a 12-month history of worsening cough and dyspnea. She is a current heavy smoker. **A**, Upper zones of the lungs show emphysema and mild patchy peripheral reticular opacities. **B**, Lower zones of the lungs show emphysema and architectural distortion with patchy peripheral reticular opacities and extensive honeycombing lesions.

“alveolitis” found in ILDs, particularly sarcoidosis.⁷⁰⁻⁷² However, ^{67}Ga lung scanning is not recommended in the routine evaluation of IPF because inflammation is not a prominent feature, the scan is difficult to interpret, the findings are not specific, and a negative scan does not exclude disease.

Ventilation-Perfusion Lung Scanning. Ventilation-perfusion lung scanning is not recommended as a routine part of the evaluation. In most parenchymal diseases, ventilation-perfusion scanning reveals an inhomogeneous reduction of blood flow, ventilation, or both.⁷² There are two types of perfusion abnormalities in IPF: nonsegmental inhomogeneities, probably due to a localized loss of the capillary bed, most often in the lower lobes; and increased perfusion of the upper lung zones, resulting from pulmonary hypertension, which induces an upward shift in the gradient of capillary perfusion. Ventilation scans often reveal patchy, nonsegmental areas of decreased ventilation, reflecting regions of airway obstruction or alveolar destruction. Patchy areas of high and low ventilation-perfusion matching are usually seen, with a few areas of well-maintained ventilation-perfusion matching. These findings of mismatching of ventilation and blood flow help explain the hypoxemia and high $\text{V}_\text{D}/\text{V}_\text{T}$ ratio found in many of these patients at rest.

Magnetic Resonance Imaging for Differentiating Inflammation and Fibrosis. Magnetic resonance imaging (MRI) has several advantages over CT, including lack of ionizing radiation and ability to identify tissue characteristics at a nuclear level that may allow for novel assessments of lung function and microstructure.⁷³ Ten patients with IPF and 16 with NSIP were examined by comparing 3-T MRI of the lung to the morphologic findings on surgical biopsy.⁷⁴ Compared with fibrotic areas, inflammation-predominant areas showed an early enhancement pattern on dynamic studies and a high-signal intensity on T2-weighted triple-inversion black-blood turbo spin-echo images compared with fibrotic areas. These results indicate that qualitative analysis of MRIs may be helpful for differentiating inflammation- and fibrosis-predominant lesions.

Imaging of Fibrogenesis by Positron Emission Tomography. The putative role of physiologic imaging using

^{18}F -2-fluoro-2-deoxy-D-glucose (FDG) positron emission tomography (PET) scans in IPF has been explored in few patients without clear results.^{75,76} In general, the lungs of patients with IPF appear to show increased uptake of FDG on PET (eFig. 63-7). Some studies have suggested that cis-4- ^{18}F -fluoro-L-proline [^{18}F -proline] may be a reliable marker for fibrosis formation. This radioligand has been tested in patients with IPF.^{55,77} PET acquisition was performed 1, 2, and 3 hours after injection of ^{18}F -proline. Surprisingly, low uptake of ^{18}F -proline was found in the lungs of all patients with IPF. The highest uptake was seen at 2 hours postinjection, with a decline at 3 hours past injection. The authors speculate that this low uptake may be due to the slow nature of fibrogenesis or to the relatively low dose of proline that can be used. Further research is necessary to know if imaging through PET has a role in the diagnosis or prognosis of ILDs.

Pulmonary Function Tests

The lung volumes (TLC, functional residual capacity, and residual volume) are reduced in IPF. Early on, the lung volumes may be normal, especially in patients with superimposed *chronic obstructive pulmonary disease* (COPD). Lung volumes are higher in smokers with IPF compared with those who have never smoked.²⁰ As mentioned previously, a group of smokers develop a combined IPF and emphysema and show almost normal lung volumes, even in advanced disease.^{52,53} Expiratory flow rates (FEV_1 and FVC) may be decreased because of the reduction in lung volume, but the FEV_1/FVC ratio is maintained. Because of the increased static elastic recoil found in these patients, flow rates (at any given lung volume) are often increased (see Figs. 63-15A and 63-17).

Patients with IPF are tachypneic, with rapid shallow breaths, probably because of increased work of breathing. This rapid respiratory rate presumably results from altered mechanical reflexes, caused by the increased elastic load, vagal mechanisms, or both, because no defined chemical basis for the hyperventilation has been identified (see Fig. 63-18).

The DL_{CO} is reduced, often before the loss of lung volume. The decrease in the DL_{CO} results from both a contraction of the pulmonary capillary volume and the presence of ventilation-perfusion abnormalities. Resting arterial blood gases are usually abnormal, revealing hypoxemia and

respiratory alkalosis. The major cause of resting hypoxemia is ventilation-perfusion mismatching; it is not due to either impaired oxygen diffusion, as was originally suspected, or to anatomic shunts. With exercise, the (A-a)PO₂ widens, and the arterial PO₂ and oxygen saturation fall. During maximal exercise, 20% to 30% of the exercise-induced widening of the (A-a)PO₂ may be caused by some impairment of oxygen diffusion. Importantly, the abnormalities identified at rest do not accurately predict the magnitude of the abnormalities seen with exercise (see Fig. 63-19). In addition, gas exchange during exercise has been demonstrated to be a sensitive parameter for following the clinical course.

In patients with IPF, a highly significant correlation has been reported between the 6-minute walk distance (6MWD) test and DL_{CO}, as well as $\dot{V}O_{2\max}$; the 6MWD is a strong predictor of mortality.⁷⁸ The 6MWD test is difficult to perform in patients with advanced lung disease, however, and variability is common.

The 15-steps Climbing Oximetry Test has been found useful for estimating ventilatory reserve in patients with COPD and for predicting postoperative complications of lung resection. In a recent study, it was shown that the desaturation measured by the 15-steps Oximetry Test in IPF patients is comparable with the desaturation measured by the cardiopulmonary exercise test and the 6MWD test, suggesting it may be a reliable tool for monitoring IPF progression and for evaluating the need for oxygen supplementation.⁷⁹ This test may serve as a surrogate marker of $\dot{V}O_{2\max}$ and an alternative to the 6MWD test in this setting.⁸⁰

During exercise, patients with IPF increase their minute ventilation primarily by increasing their respiratory frequency (see Fig. 63-18). This method of increase differs from that in normal subjects, in whom ventilation increases during mild exercise by an increase in the tidal volume (VT) rather than respiratory rate. Thus, patients with IPF have elevated minute ventilation during exercise that is in part related to the increase in VD. In addition, the VD/VT ratio is increased at rest and is maintained or decreases only slightly with exercise. Occasionally, the VD/VT ratio increases in ILDs that have a prominent pulmonary vascular component, such as scleroderma or PLCH.

Pulmonary Hemodynamics

Recent evidence suggests *pulmonary hypertension due to IPF* (PH-IPF) is relatively common and may contribute substantially to functional status, quality of life, morbidity, and mortality.⁸¹⁻⁸⁵ (See Chapter 59.) The prevalence of PH complicating the course of patients with IPF has been reported in between 32% and 85% of patients, being more frequent in advanced disease.⁸⁵ The most appropriate method to detect PH noninvasively is transthoracic (Doppler) echocardiography. Unfortunately, echocardiography may be inaccurate in estimating pulmonary arterial systolic pressure in patients with ILD.⁸⁶ Right heart catheterization is the “gold standard” for the hemodynamic evaluation of the pulmonary circulation and diagnosis of PH but is an invasive technique. Right heart catheterization may be necessary, however, to document the severity of PH and potential right ventricular dysfunction. Abnormalities in gas exchange and exercise capacity seem to have a significant

association with PH-IPF. Thus, exaggerated exercise oxygen desaturation, out-of-proportion reduction of DL_{CO}, and supplemental oxygen requirement should raise suspicion of (and may be a useful surrogate for) the presence of underlying PH.^{83,85} Brain natriuretic peptide concentrations predicted moderate to severe PH with 100% sensitivity and high specificity (89%) in a small cohort of patients with pulmonary fibrosis.⁸⁷ This study requires further validation.

Pathologic vascular findings in IPF consist of changes in the arteries, arterioles, and venules, as well as destruction of the capillary bed.⁸⁸ Adventitial thickening around the pulmonary vessels reflects an increase of connective tissue. Smooth muscle cells hypertrophy and proliferate, and collagen and elastin accumulate in the media of the small muscular pulmonary arteries. Distal pulmonary arterioles become muscularized (see Fig. 59-4E,F). In addition, there may be extensive intimal hyperplasia, fibrosis, and reduplication of the inner elastic lamina in the small muscular pulmonary arteries in IPF. Increased hemosiderin deposition and alveolar septal capillary density have been associated with higher right ventricular systolic pressure (as assessed by transthoracic echocardiography) and may represent histologic correlates of pulmonary hypertension in IPF.⁸⁹

Supplemental oxygen is the most obvious choice for prevention or treatment of PH; however, there are no data supporting favorable effects of oxygen on survival in PH-IPF. Vasodilators agents are currently being studied, but one must recognize that decreased physiologic vasoconstriction in low ventilation-perfusion lung units may worsen shunt and hypoxemia in IPF.^{84,85,90}

Endothelin-1 (ET-1) receptor antagonists have been useful in patients with other types of pulmonary hypertension, mostly in primary PAH or PAH associated with connective tissue disease. Clinical trials in PH-IPF are ongoing (Table 63-9). Prostacyclin (*prostaglandin I₂* [PGI₂]) analogues used via inhalation could maintain (or even improve) ventilation-perfusion matching and could have a beneficial effect targeting PH. In one study, inhaled iloprost decreased mean pulmonary artery pressure without changes in shunt flow,⁹¹ suggesting the utility of selective pulmonary vasodilation in patients with PH-IPF. Sildenafil, a phosphodiesterase-5 inhibitor, promotes vasodilation and decreases smooth muscle proliferation and vascular remodeling. In an open-label study of treatment with sildenafil for 3 months in a small cohort of patients with PH-IPF, a modest but significant improvement in 6MWD was noticed.⁹² In a subsequent randomized clinical trial, sildenafil therapy did not show a benefit for the primary outcome (increase in 6MWD of 20% or more), but a small yet significant improvement was noted in arterial oxygenation, diffusing capacity, dyspnea, and quality of life.⁹³ Several other randomized clinical trials are currently ongoing (see Table 63-9) to learn whether any therapies will be useful in PH-IPF (see Chapter 59).

Abnormalities during Sleep

Many patients with IPF, especially those with low daytime arterial oxygen saturation or a history of snoring during sleep, develop sleep disturbances characterized by reduced rapid eye movement sleep, lighter and more fragmented

Table 63-9 Ongoing Clinical Trials in Patients with Idiopathic Pulmonary Fibrosis

sleep, and hypoxemia during rapid eye movement sleep.^{94,95} Severe hypoxemia can be seen in the absence of obstructive sleep apnea or changes in breathing pattern. Tachypnea persists during sleep. Identification and correction of the sleep disturbance may reduce morbidity and improve quality of life and patient survival. In one study, obstructive sleep apnea was confirmed in two thirds of IPF patients with complaints suggestive of sleep apnea.⁹⁶ An increased body mass index and a significant impairment in pulmonary function testing may be predictors of obstructive sleep apnea in this population.⁹⁶

Histopathology

The gross appearance of the lungs in IPF reveals a distinctive nodular pleural surface, sometimes resembling cirrhosis of the liver, due to contraction of the fibrotic septa. The histopathologic pattern in IPF is UIP. UIP is characterized by a pattern quite distinguishable even on low-power magnification because of its characteristic heterogeneous, predominantly subpleural and paraseptal distribution (Fig. 63-22). This striking heterogeneous appearance is characterized by the presence of small areas of residual normal or nearly normal lung tissue interspersed among extensively

Figure 63-22 Usual interstitial pneumonia pattern often shows a striking subpleural distribution. This low-power photomicrograph is from an area without the usual remodeling of the lung architecture with cystic (honeycomb) changes. The visceral pleura is at the bottom of the image. (Courtesy Thomas V. Colby, MD, Mayo Clinic, Scottsdale, AZ.)

Figure 63-24 Photomicrograph of usual interstitial pneumonia. Two fibroblastic foci of loose organizing connective tissue (arrows) are seen adjacent to an area of dense fibrosis (asterisks). (Courtesy Thomas V. Colby, MD, Mayo Clinic, Scottsdale, AZ.)

Figure 63-23 Photomicrograph of usual interstitial pneumonia. Residual lymphoplasmacytic inflammation and collagen deposition is seen broadening alveolar walls. (Original magnification $\times 10$.)

Figure 63-25 Photomicrograph of honeycomb lung in idiopathic pulmonary fibrosis. There is total disruption of the lung architecture by bands of fibrous tissue forming cystic spaces. The spaces are lined by metaplastic epithelium. (Original magnification $\times 10$.)

scarred parenchyma, which may show microscopic honeycombing characterized by enlarged air spaces lined by bronchiolar epithelium, often filled with mucin and variable numbers of inflammatory cells with abutting areas of active proliferation of fibroblasts and myofibroblasts (Figs. 63-23, 63-24, and 63-25).^{16,33,36} These discrete areas of fibroblastic proliferation have been termed *fibroblastic foci* and are essential to the histopathologic diagnosis of UIP³⁶ (see Fig. 63-24). Fibroblastic foci are composed of small dome-shaped collections of spindle-shaped fibroblasts and myofibroblasts within myxoid stroma, covered by hyperplastic alveolar lining cells. Generally, interstitial inflammation is minimal in UIP; if inflammation is present in significant amounts, the diagnosis of UIP in IPF should be reconsidered and other causes of a UIP pattern such as chronic HP and collagen vascular disease should be reconsidered. However, chronic inflammation, lymphoid aggregates with germinal centers, and even acute inflammation may be prominent around honeycomb areas, likely related to poor clearance from the areas of scarred lung.³⁶

Bronchogenic carcinoma (all histologic types) has been identified with increased frequency in advanced IPF (eFig. 63-8).⁹⁷⁻⁹⁹ It has been postulated that carcinoma arises from the metaplastic bronchiolar epithelium that develops in these patients, but the pathogenic mechanisms are unclear. Interestingly, a number of the reported cases have been reported in patients with familial IPF.

Etiologic Factors and Pathogenic Mechanisms

The inciting factors in the development of IPF are unknown. A widely held hypothesis is that this disorder develops in susceptible individuals following some unknown stimuli. Inciting agents initiate an uncontrolled cascade of events that evolve to the fibrotic process. Smoking presents the most significant association with IPF, particularly for individuals who were ever smokers, with *odds ratios* (ORs) varying from 1.6 to 9.4.¹⁰⁰ The same association has been found in familial pulmonary fibrosis. In a family-based case-control study of familial pulmonary fibrosis, Steele and colleagues⁴⁷ identified 111 families, with 309 affected and 360

unaffected individuals. Adjusting for age and gender, ever smoking was strongly associated with pulmonary fibrosis (OR, 3.6; 95% confidence interval [CI], 1.3-9.8). Some occupational and environmental exposures—primarily to wood and metal dusts—have also shown increased association with IPF.⁴⁷ The presence of Epstein-Barr virus found in some patients has led to speculation that chronic viral infection might play a role in the etiology of IPF,¹⁰¹ but this virus has also been found in other fibrotic lung diseases, as well as in many controls. A higher incidence of *gastroesophageal reflux* (GER) has been found in patients with IPF.¹⁰² GER is frequent, however, in the normal population, as well as in patients with other advanced lung diseases, including cystic fibrosis, COPD, and fibrosis associated with scleroderma.¹⁰³

The role of host genetic factors and their interactions with environmental factors leading to IPF is unknown. Numerous gene polymorphisms have been examined, and only a few of them have demonstrated a confirmed (usually weak) association. Moreover, putative associations have not generally been corroborated in independent cohorts. Interestingly, two recent studies performed in independent cohorts suggest that a common polymorphism in the promoter region of an airway mucin gene *MUC5B* may be associated with familial pulmonary fibrosis and idiopathic pulmonary fibrosis, although the link with disease pathogenesis is unknown.¹⁰⁴⁻¹⁰⁶ It has been suggested that this polymorphism in *MUC5B* may be associated with improved survival.¹⁰⁷ Additional studies have shown that the *MUC5B* promoter polymorphism is associated with ILD in the general population, and it does not appear to be influenced by cigarette smoking.¹⁰⁸

An important advance in our understanding of ILD has been the recognition that UIP appears to be a distinct pathophysiologic entity characterized by minimal inflammation and chronic fibroproliferation due to abnormal parenchymal wound healing.^{109,110} This paradigm suggests that the pathologic process of UIP is the result of persistent remodeling (abnormal wound healing) of the lung parenchyma. Multiple “microinjuries” damage and activate alveolar epithelial cells, which in turn provoke a profibrotic microenvironment.¹¹¹ Alveolar epithelial cells secrete growth factors and induce migration and proliferation of fibroblasts and differentiation into myofibroblasts. Aggregates of subepithelial fibroblasts-myofibroblasts (fibroblastic foci) and alveolar epithelial cells produce matrix-metalloproteinases 2 and 9 that may increase basement membrane disruption and allow fibroblast-myofibroblast migration into the alveolar spaces. In addition, alveolar epithelial cells induce an antifibrinolytic environment in the alveolar spaces, enhancing wound clot formation. Current evidence suggests that the tissue-factor-dependent extrinsic pathway is the predominant mechanism by which the coagulation cascade is locally activated in the lungs of patients with pulmonary fibrosis.¹¹² Both intra-alveolar and interstitial myofibroblasts secrete extracellular matrix proteins, mainly collagens. An imbalance between interstitial collagenases and tissue inhibitors of metalloproteinases provokes the progressive deposition of extracellular matrix.¹¹³ Signals responsible for myofibroblast apoptosis seem to be absent or delayed in UIP, increasing cell survival.¹¹⁴ These myofibroblasts produce angiotensinogen and hydrogen peroxide that

have been implied in alveolar epithelial cell death, further impairing reepithelialization.^{115,116} Although the molecular mechanisms that lead to end-stage pulmonary fibrosis in the IIPs are poorly understood, data support this “abnormal wound healing” hypothesis in UIP.^{45,111,117} At least in part, the abnormal communication between alveolar epithelial cells and myofibroblasts may be provoked by an aberrant recapitulation of embryologic programs.¹¹⁸⁻¹²⁰

One of the intriguing observations regarding IPF is that the disease is clearly associated with aging; it usually appears in individuals older than 50 years, reaching a peak in subjects of 60 to 65 years old. In this context, two recent studies have shown that mutations in the genes encoding telomerase components are implicated in familial pulmonary fibrosis.^{121,122} It has also been shown that patients with sporadic IPF have shorter leukocyte telomeres than age-matched controls and that some of them (10% to 25%) had telomere lengths below the first percentile for their age.^{123,124} Importantly, it was also determined that IPF patients had short telomeres in alveolar epithelial cells, suggesting that these cells may be the main lung culprit of this pathologic process.¹²³ Telomeres play a central role in cell fate and aging by adjusting the cellular response to stress and growth stimulation on the basis of previous cell divisions and DNA damage; their shortening has been associated with aging and several diseases.^{125,126}

Diagnosis

The most definitive method of establishing a diagnosis is by surgical lung biopsy, but the presence of typical features of a UIP pattern on HRCT may obviate the need for biopsy.^{32,59,127} Thoracoscopic or open-lung biopsy is indicated because it provides an accurate diagnosis; it excludes neoplastic and infectious processes that occasionally mimic chronic, progressive interstitial disease; it may also identify a more treatable process than originally suspected (e.g., chronic hypersensitivity pneumonitis); and it provides a better assessment of disease activity.^{16,31,32,128} Studies have addressed the accuracy of the combined clinical and radiographic diagnosis of IPF.^{59,61} In both studies, clinicians were blinded to the results of the surgical lung biopsies, which were used as the gold standard for diagnosis. The positive predictive value of a confident clinical diagnosis of IPF was 87% and 96% among pulmonologists and radiologists with specific expertise in ILD, respectively.¹²⁹ The clinical diagnosis of IPF had a sensitivity of 62% and a specificity of 97% compared with the radiologic diagnosis, which had a sensitivity of 70% and a specificity of 90%.⁶¹ As recognition of the HRCT features has improved, it has been suggested that—in the appropriate clinical setting and with radiologist expert in IPF diagnosis—the predictive value of HRCT for the diagnosis of IPF is good, even in patients with *possible* UIP pattern on HRCT (i.e., meeting ATS/ERS criteria for IPF but with 5% or less honeycombing on HRCT).¹³⁰

Collectively, these studies argue that, when the clinical and radiographic diagnoses are consistent, IPF can be confidently diagnosed. They also demonstrate, however, that this consistency is present in only about half of patients with biopsy-confirmed UIP. Furthermore, experts in the field performed these studies and it is unclear how the outcome would vary with community physicians less familiar with these processes. In this context, significant

disagreement has been reported regarding the diagnosis of IIPs between physicians based in communities compared with those in academic centers.¹³¹ Importantly, community physicians were more likely to make a diagnosis of IPF, which has important implications, because individual patients with other ILDs (e.g., hypersensitivity pneumonitis, NSIP, or collagen vascular disease–associated ILD) are more likely to respond to immunosuppressive treatment, whereas patients with IPF should be referred, whenever possible, for participation in clinical therapeutic trials or for evaluation for lung transplant. In addition, this study also confirms that a multidisciplinary team approach among clinicians, radiologists, and pathologists improves interobserver agreement and enhances diagnosis specificity.¹³¹

Staging of Disease Activity and Predicting Outcome

The long-term survival in IPF is distinctly poor, with only a 20% to 30% survival 5 years after the time of diagnosis.^{16,32,45,132-134} However, the rate of progression is variable. Attempts to predict who will respond to treatment have been largely disappointing primarily because the disease is relentlessly progressive with all the therapies used until now.

Clinical Features. Younger patients tend to have less fibrosis than do older patients, and younger patients and women survive longer than older patients and men. In a recent study, it was found that the percentage of monthly worsening in oxygen saturation is high in males, suggesting differences in disease progression according to gender.¹³⁵ Current smoking (i.e., at the time of presentation) was associated with improved survival in patients with IPF, whereas heavy smoking (i.e., higher number of pack-years) was associated with a worse prognosis.²³ In addition, pulmonary fibrosis combined with emphysema and the accelerated variant of IPF that display the worst survival seems to be more frequent in smokers.^{52,53,136} The *Medical Research Council* (MRC) Chronic Dyspnea Score estimated at the time of diagnosis is predictive of survival and may aid clinicians in assessing the prognosis of new cases of IPF.¹³⁷

Serum Studies. The presence of immunologic markers, including autoantibodies, elevated sedimentation rates, circulating immune complexes, and increased serum immunoglobulins, has not been shown to correlate with the overall natural history of IPF.

Serum *surfactant protein* (SP)-A and SP-D have prognostic value for mortality in patients with IPF.¹³⁸ A recent study showed that after controlling for known clinical predictors of mortality, an increased serum SP-A level is a strong and independent predictor of early mortality among patients with IPF. A prediction model containing SP-A and SP-D was substantially superior to a model with clinical predictors alone.¹³⁹ Also, serum CCL18 concentrations seem to have a predictive value in IPF with higher mortality observed in patients with concentrations above 150 ng/mL.¹⁴⁰

Chest Radiography and High-Resolution Computed Tomography Scanning. A general pattern of evolution is seen with serial chest radiography. The early changes include hazy opacities with reduction in lung volumes that

progress to a reticular pattern and finally end in coarser, cystic areas of honeycombed lung (eFig. 63-9). Unfortunately, the chest radiograph is not a useful monitor of the degree and extent of lesions. In fact, the only radiographic abnormality that correlates with the histologic pattern is honeycombing (eFig. 63-10). Furthermore, chest radiography may demonstrate no changes despite clinically apparent physiologic deterioration. Another major problem with using chest radiography to follow the disease course or to estimate the stage of disease is that there is considerable interobserver variability in the interpretation of these studies.

HRCT scanning in IPF may be useful in staging disease activity. The finding of a higher extent of ground-glass opacities and a lower extent of reticular opacities on the initial HRCT identifies those patients with early disease (see eFig. 63-1) who are the most likely to survive longer and respond (if transiently) to corticosteroids.¹⁴¹ Patients with a typical HRCT appearance of UIP experience the highest mortality.⁶⁷

It was shown by univariate logistic regression analysis that a greater extent of fibrosis by HRCT predicted a greater short-term mortality during follow-up.¹⁴² The multivariate logistic regression analysis showed that the single best predictor of mortality during follow-up was the visual extent of fibrosis on CT images, and there was little additional predictive power to be gained from the more quantitative measures.¹⁴²

Pulmonary Physiologic Tests. Reductions in the vital capacity correlate with the degree of fibrosis present and show a relationship with the overall histologic derangements.^{143,144} A significant reduction in the vital capacity (<50% of predicted) is associated with pulmonary hypertension and a reduced 2-year survival. Patients with normal DL_{CO} values usually do not have significant gas exchange abnormalities, whereas patients with DL_{CO} below 70% of predicted frequently have such changes at rest or with exercise. Survival is longer in patients with a more normal DL_{CO} (>45% of predicted value). A marked reduction of the DL_{CO} and resting hypoxemia are associated with pulmonary hypertension and decreased survival.

Patients with advanced disease and severe fibrosis have greater abnormalities of the $(A-a)PO_2$ when compared with those with early disease and preserved lung architecture. When compared with other indices of lung function, alterations in gas exchange during exercise correlate best with histopathologic findings. Serial measurements of gas exchange during exercise also appear to be the best predictors of survival. It has been demonstrated that the predictive ability of serial changes in physiology varies when patients are stratified by the presence/absence of desaturation during a baseline 66-minute walk test; for patients with baseline saturation less than 88%, the strongest observed predictor of mortality was serial change in DL_{CO} and, for patients with saturation greater than 88% during their baseline walk test, serial decreases in FVC and increases in desaturation area significantly predicted subsequent mortality.¹⁴⁵ In summary, pulmonary function testing is useful in establishing the presence of impairment in IPF and following its course and response to therapy. The severity of the initial abnormalities in FVC, DL_{CO} , arterial PO_2 , and

(A–a)PO₂, as well as oxygen desaturation on a 6MWD test,⁷⁸ correlate with poorer survival. Likewise, changes in DL_{CO}, TLC, FVC, arterial PO₂, oxygen saturation, and (A–a)PO₂ during follow-up are predictive of survival time after adjustment for baseline values.^{144,146}

Bronchoalveolar Lavage. It has been suggested that the BAL cellular constituents reflect the state of the pulmonary inflammatory response. Unfortunately, many studies have failed to demonstrate a clear distinction between diseases on the basis of the predominant cell type present in the lavage specimens. IPF is characterized by a severalfold increase in the total number of inflammatory cells recovered from the respiratory tract with an increase in the percentage of neutrophils and eosinophils.^{16,26} Studies evaluating the association of BAL fluid cellular constituents and mortality have yielded conflicting results about the prognostic value of BAL and were limited by the size of the study cohort and duration of follow-up.¹⁴⁷

Turner-Warwick and Haslam¹⁴⁸ found that patients who failed to improve had elevated neutrophil and eosinophil counts throughout their course. More recent findings tend to confirm these findings, suggesting that an elevated percentage of neutrophils in the BAL may be an independent predictor of early mortality among persons with IPF.¹⁴⁹ The impact was most important in the first year of follow-up and attenuated with time.

In one study, it was found that SP-A is reduced in IPF, and decreases in its concentration referenced to total phospholipid (a marker of surfactant to normalize to the surface sampled by lavage and recovery) predict an adverse clinical outcome and poorer survival.¹³⁸

Histopathology. Until recently, no specific histologic feature, other than end-stage fibrosis and honeycombing, has been shown to correlate with survival in UIP.^{23,109} It has been proposed that the earliest and most characteristic manifestation of ongoing lung injury in UIP is the development of multiple fibroblastic foci.^{36,150} The prognostic significance of these aggregates of fibroblasts and myofibroblasts in surgical lung biopsies from patients with IPF is unclear, and several studies have given contradictory results.^{151–155} The effect of sample size, tissue sampling bias, and the different techniques for assessing the number of foci may account for these results. In general, detailed quantification of fibroblast foci on surgical lung biopsies may not be a consistent predictor of patient survival in this disease.

Prediction Models. Several investigators have attempted to identify parameters that best predict the clinical course and prognosis of IPF.^{78,145,146,156,157} Individual changes in dyspnea score, TLC, FVC, arterial PO₂, oxygen saturation, or (A–a)PO₂ over 6 and 12 months may be useful as surrogate end points in monitoring therapeutic efficacy in individual patients. Prediction models based on combining multiple baseline clinical, radiologic, or physiologic measurements have been derived from large groups of carefully selected patients with IPF and appear to perform well as predictors of outcome.^{23,157} Using hierarchical multivariable analysis of clinical, radiologic, and extensive physiologic variables, King and associates²³ developed a model that allows clinicians to make more precise prognostic estimations about

patients with IPF. This model included the parameters of age, smoking history, clubbing, extent of profusion of interstitial opacities, presence or absence of pulmonary hypertension on the chest radiograph, percent predicted TLC, and arterial PO₂ at the end of maximal exercise. Although the clinical, radiologic, and physiologic score is an accurate predictor of survival in IPF, it requires both detailed radiographic analysis and exercise physiologic measurements, neither of which is readily available to many physicians. This may limit its utility as a predictor of survival for those in general practice.

Wells and coworkers¹⁵⁷ identified a composite physiologic index closely reflecting the morphologic extent of pulmonary fibrosis while accounting for the extent of emphysema (a finding commonly present in smokers with IPF). The composite physiologic index correlated strongly with extent of disease on CT and mortality and was more accurate than any individual pulmonary function test.¹⁵⁷ However, its value in clinical practice appears limited.

Recently, Ley and colleagues¹⁵⁸ proposed a multidimensional prognostic staging system for IPF using only commonly measured clinical and physiologic variables (age, gender, FVC, and DL_{CO}). A simple-to-use staging system such as this may help inform prognosis and guide management decisions such as those about the appropriate timing of lung transplantation.

Outcome and Causes of Death. Clinical deterioration in patients with IPF is expected. Most patients experience episodes of worsening shortness of breath, decreased exercise tolerance, or other decline in functional status during the course of their illness.¹⁴³ Disease progression may be difficult to distinguish from disease-associated complications and adverse effects of therapy.¹⁵⁹ Death rates are higher in men, higher with increasing age, and highest in the winter, even when infections are excluded.¹⁴³ Frequent hospitalizations for respiratory problems are common events and are often associated with death.^{143,160,161}

In a study of 42 consecutive patients who died with IPF over a 9-year period, autopsies showed that IPF by itself was the immediate cause of death in half of the patients either from an acute exacerbation (see “Acute Exacerbations of Idiopathic Pulmonary Fibrosis” later) or from the gradual progression of the disease.¹⁶² Other respiratory causes of death included pneumonia and aspiration. Cardiovascular disease including arrhythmia, myocardial infarction, and severe cor pulmonale was found to be the cause of death in 20% of subjects. Evidence of pulmonary hypertension was present on autopsy in 45% of patients and was the immediate cause of death in two of them. Pulmonary embolism appears to be relatively common in IPF lung transplant recipients, although its prevalence is unknown.¹⁶³ Importantly, it has been shown that patients with IPF have a higher prevalence of coronary artery disease.¹⁶⁴ Also, patients with clinically stable IPF exhibit not only right ventricular diastolic and systolic dysfunction but also impaired left ventricular diastolic filling, while the systolic function is preserved.¹⁶⁵

Therapeutic Approach

IPF is a progressive and fatal disorder without spontaneous remission, and no therapy to date has been shown to be

effective.^{16,45,166} Although the natural history of IPF has not been appropriately defined, data thus far suggest the median survival after diagnosis, with or without treatment, is 2 to 3 years.^{16,133,134,143} Any therapy of IPF, regardless of the agent used, requires at least 1 year before its effectiveness can be assessed.

Corticosteroids. Although corticosteroids alone were the mainstay for the treatment of IPF for many years, there was never any randomized, placebo-controlled study to support their use.^{167,168} The use of anti-inflammatory therapies in this disease was based on the concept that a chronic inflammatory infiltrate led to progressive extracellular matrix deposition. However, the response to corticosteroid treatment in IPF has been almost uniformly poor.¹⁶⁹ In addition, significant complications can result from corticosteroid therapy, affecting the quality of life. Currently, there is no indication for the use of corticosteroids alone in the treatment of IPF.

Immunomodulatory and Antifibrotic Agents. Because of the poor responsiveness of IPF to corticosteroids, immunomodulatory agents (azathioprine or cyclophosphamide alone or in combination with corticosteroids) have been tried.¹⁷⁰⁻¹⁷³

Several adequate randomized, controlled clinical trials of sufficient numbers of patients with IPF have been performed using putative “antifibrotic” drugs, but none thus far has shown significant improvements in outcome. Combination therapy with prednisone, azathioprine, and *N-acetylcysteine* (NAC) was suggested as a reasonable choice for patients with mild to moderate disease.¹⁷⁴ However, a recent study showed the combination therapy (prednisone, azathioprine, and NAC) to be associated with an increased rate of death and hospitalizations compared with placebo.¹⁷⁵ In this three-arm study of patients with mild to moderate impairment in lung function, combination therapy was compared with NAC alone and placebo. Enrollment into the combination therapy group was halted when an interim analysis revealed increased rate of death and hospitalization compared with placebo. These results argue against the use of such combination therapy in patients with IPF. The comparison of NAC alone versus placebo is ongoing.

AZATHIOPRINE. Azathioprine is a purine analogue that appears to act by the substitution of purines in DNA synthesis and by inhibiting adenine deaminase, which affects lymphocyte functions. Although older studies suggested azathioprine and low-dose prednisone might be useful in the treatment of patients with IPF,¹⁷¹ this drug alone or combined with corticosteroids is not currently indicated for this disorder.

N-ACETYLCYSTEINE. In a double-blind, randomized, placebo-controlled multicenter study, it was found that NAC, a molecular precursor to the naturally occurring antioxidant glutathione, added to prednisone and azathioprine at a dose of 600 mg three times daily, preserves vital capacity and DL_{CO} better than does prednisone and azathioprine alone after approximately 1 year of follow-up.¹⁷⁴ No mortality benefit was identified in this study. A placebo-controlled study of NAC administered orally alone in an IPF population does not support its use for the preservation

of FVC in IPF patients with mild-to-moderate physiologic abnormalities.¹⁷⁶

CYCLOPHOSPHAMIDE. Cyclophosphamide was formerly used as a second-line drug in patients who either failed or could not tolerate corticosteroid treatment. Cyclophosphamide is an alkylating agent of the nitrogen mustard group that is absorbed orally and activated in the liver to several cytotoxic compounds. Its mode of action is the depletion of lymphocytes, thereby suppressing lymphocyte function. The recommended dose is 2 mg/kg/day given orally as a single dose, usually with oral prednisone at 0.25 mg/kg/day. Few data are available on the length of therapy. However, a large retrospective study of well-defined, matched patients with IPF suggested that treatment with combined corticosteroid and cyclophosphamide therapy does not improve survival compared with untreated patients.¹⁷⁰

In addition, cyclophosphamide therapy also has severe side effects including leukopenia, thrombocytopenia, hematuria secondary to hemorrhagic cystitis, gastrointestinal symptoms (including anorexia, nausea, and vomiting), bone marrow suppression, azoospermia and amenorrhea, infection, and the development of a hematologic malignant disease.

Other Agents. A number of other immunosuppressive or putative antifibrotic agents have been reported in individual cases or in small groups of patients with IPF without success. In vitro studies suggest several mechanisms by which *colchicine* may interrupt the processes of collagen synthesis and deposition; it may have anti-inflammatory effects as well. On the basis of these mechanisms of action, colchicine has been used as a potential therapeutic agent in IPF, but there are no data affirming the efficacy of colchicine in IPF.¹⁷⁷⁻¹⁷⁹ *Penicillamine* inhibits collagen synthesis by interfering with collagen cross-linking and is a suppressor of T-cell function. Limited studies have not shown efficacy in IPF.¹⁷⁹ *Captopril* inhibits the angiotensin-converting enzyme and completely abrogates Fas-induced apoptosis in human alveolar epithelial cells. It has also been shown to inhibit fibroblast proliferation in vitro and reduce the fibrotic lung response in vivo. A retrospective study failed to demonstrate a beneficial effect of ACE inhibitors on survival of patients with IPF.¹⁸⁰

Recently, the efficacy of thalidomide therapy in suppressing cough in patients with IPF was evaluated in a 24-week, randomized, double-blind, two-period crossover trial of 98 participants. Thalidomide therapy was associated with improved cough and quality of life in patients with IPF. A larger trial is planned to confirm the beneficial effects observed in this trial.

New Therapeutic Approaches. On the basis of new knowledge about the pathogenic mechanisms involved in IPF and on the poor results obtained with immunosuppressive drugs, newer immunomodulatory or antifibrotic agents have been tried in patients with IPF.

PIRFENIDONE. Pirfenidone (5-methyl-1-phenyl-2-[1H]-pyridone) is a novel antifibrotic and anti-inflammatory agent that inhibits the progression of fibrosis in animal models. Several clinical trials showed promise in stabilizing the lung function and reducing the number of patients who

experienced acute exacerbation of their disease.^{181,182} A randomized clinical trial from Japan noted a difference in progression-free survival in favor of the high-dose pirfenidone group compared with placebo.¹⁸³ Two additional international randomized clinical trials of pirfenidone have since been completed enrolling 435 and 344 IPF patients, respectively.¹⁸⁴ In one of these trials, pirfenidone achieved the primary end point of absolute change from baseline in percent-predicted FVC. The second trial did not meet this same primary end point. A recent phase 3 randomized, double-blind, placebo-controlled trial evaluating pirfenidone in patients with IPF observed reduced disease progression as reflected by better lung volume, improved exercise tolerance, and better progression-free survival.¹⁸⁵ Pirfenidone has been approved for the treatment of IPF in the United States, Europe, and Japan.

NINTEDANIB. Nintedanib (BIBF-1120) is a tyrosine kinase inhibitor that targets the platelet-derived growth factor receptor, vascular endothelial growth factor receptors, and fibroblast growth factor receptors.¹⁸⁶ A 12-month, randomized, double-blind, placebo-controlled, phase 2 trial with 432 IPF patients was recently completed and included four groups assigned to different doses of BIBF-1120.¹⁸⁷ The primary end point was annual rate of decline in FVC. A trend toward a reduction in the decline of lung function with fewer acute exacerbations and preserved quality of life was associated with the highest-dose (150 mg twice daily) regimen of BIBF-1120. In two recent replicate Phase III, multinational, randomized, placebo-controlled, parallel-group trials (INPULSIS-1 and INPULSIS-2), nintedanib slowed disease progression by significantly reducing the rate of decline in FVC.¹⁸⁸ Nintedanib has been approved for the treatment of IPF in the United States.

INTERFERON- γ . A large, controlled trial with *interferon* (IFN) γ -1b noted no difference in the primary end point (progression-free survival) or in most secondary end points.¹⁸⁹ In patients defined as having milder disease (FVC > 55%; defined post hoc), a potential survival benefit was suggested.¹⁹⁰ However, a much larger controlled trial (826 patients) with survival as the primary end point was recently discontinued due to a lack of efficacy. The overall mortality was 14.5% in the IFN γ -1b and 12.7% in the placebo group.¹⁹¹ A trial using IFN- γ as a nebulized mist is now ongoing (see Table 63-9).

ENDOTHELIN-RECEPTOR ANTAGONISTS. ET-1 contributes to the fibrotic phenotype of fibroblasts and is a downstream mediator of profibrotic responses to *transforming growth factor- β* (TGF- β).¹⁹² In a rat model, it was found that ET-1 is involved in the pathogenesis of lung fibrosis and that blockage of its receptors reduces the fibrosis.¹⁹³ *Bosentan* is a dual ET-1 receptor antagonist (ET_A and ET_B) that has been shown to be effective in the treatment of idiopathic PAH. In a large, randomized, multinational, double-blind, placebo-controlled trial in patients with IPF, bosentan did not show an improvement over placebo with respect to 6MWD (primary end point), but patients treated with this drug showed a tendency to delayed time to death or disease progression, a predefined secondary end point. A surprising and unexplained finding was that this treatment effect was significant in the subset of patients who underwent surgical lung biopsy for confirmation of diagnosis. In a subsequent prospective double-blind, placebo-controlled trial, 616

patients with IPF confirmed by surgical lung biopsy and without extensive honeycombing on HRCT were randomized 2:1 (bosentan to placebo).¹⁹⁴ Bosentan was well tolerated, but there was no difference in the treatment groups in primary end points (time to IPF worsening or death). There were no treatment effects on health-related quality of life or dyspnea.

ETANERCEPT. The introduction of targeted biologic agents directed against *tumor necrosis factor- α* (TNF- α) has represented a novel and exciting avenue for the treatment of a variety of diseases. Elevated levels of this cytokine have been detected in experimental lung fibrosis and in patients with IPF as well. The effect of etanercept, a recombinant soluble human TNF receptor that binds to TNF and neutralizes its activity in vitro, was explored in IPF patients.¹⁹⁵ Sixty-five patients (etanercept, $n = 34$; placebo, $n = 31$) completed the 48 weeks of treatment. No statistically significant differences were observed between treatment groups in the three primary end points: changes in FVC%, DL_{CO}%, and the (A-a)PO₂ (at rest) at 48 weeks. However, this can be due in part to the modest number of subjects included in the trial. In posthoc analysis, using rate of disease progression by death or absolute reduction in FVC (L), a tendency favoring etanercept was observed.

IMATINIB. Imatinib is a competitive tyrosine-kinase inhibitor developed in late 1990s that inhibits BCR-Abl tyrosine kinase, the constitutively active fusion product in chronic myelogenous leukemia.¹⁹⁶ It also inhibits tyrosine kinase for platelet-derived growth factor, c-Kit, and stem cell factor. Imatinib is used in the treatment of Philadelphia chromosome-positive chronic myeloid leukemia, c-kit-positive gastrointestinal stromal tumors, and other proliferative disorders. Imatinib has also been shown to be capable of blocking the TGF- β pathway and preventing bleomycin-mediated pulmonary fibrosis in an animal model.¹⁹⁷ A multicenter clinical trial comparing imatinib with placebo over 96 weeks in 119 patients was completed with the primary endpoint defined as time to progression (with progression defined as a 10% decline in percent predicted FVC from baseline) or time to death. There was no effect of imatinib therapy on the change in FVC or survival.¹⁹⁸

ANTICOAGULANTS. Excessive coagulant activity is thought to play a role in orchestrating fibrotic responses to tissue injury.¹⁹⁹ In 2005, Kubo and colleagues reported anticoagulant therapy was associated with better survival in a nonblinded prospective study of 56 IPF patients assigned to prednisolone alone or prednisolone plus anticoagulant therapy.^{199a} There appeared to be a substantial reduction in mortality associated with acute exacerbations of IPF. A subsequent randomized, double-blind, placebo-controlled study failed to show benefit of anticoagulant therapy in patients with progressive IPF.²⁰⁰ The study was terminated when an interim analysis showed an increase in mortality for those randomized to warfarin and a low likelihood of benefit. Ongoing clinical trials are summarized in Table 63-9.

TREATMENT OF GASTROESOPHAGEAL REFLUX. There is equipoise about how aggressively to pursue the diagnosis of gastroesophageal reflux and how aggressively to treat gastroesophageal reflux in patients with IPF. However, growing evidence suggests that there is a clinical benefit to treatment of gastroesophageal reflux with *proton pump inhibitors*

(PPIs) or *histamine-receptor-2* (H₂) blocker, despite concerns about the risks to medical treatment with PPIs (e.g., increased risk for community-acquired or hip fracture).^{6,102,201,202} Lee and coworkers²⁰¹ have shown that IPF patients taking antiacid treatment at baseline had a smaller decrease in FVC than did those not taking antacid treatment, less evidence of radiologic fibrosis, and a longer survival time.⁶ It is unknown if other measures used in the management of gastroesophageal reflux, such as lifestyle modifications (e.g., small meals, avoidance of certain foods and alcohol), other pharmaceutical interventions (e.g., prokinetics), or surgical barrier creation (e.g., Nissen fundoplication), have a role in the treatment of patients with IPF.^{202,203}

Lung Transplantation (see Chapter 106)

Since the late 1980s, lung transplantation has been used for the management of a wide range of severe lung disorders with progressive disease unresponsive to pharmacologic treatment, with evidence supporting quality of life and survival benefit for lung transplant recipients. The American Thoracic Society has published guidelines for the selection of IPF patients who should be considered potential transplant candidates.²⁰⁴

Unfortunately, given the scarcity of donors and the aging and disease complications of IPF patients, transplantation is indicated only in carefully selected patients. Early referral for consideration of transplant is highly desirable. It allows an orderly process for assessment, management of areas of concern, and patient education before active listing.²⁰⁴ Transplantation should be considered for patients who have signs or symptoms of progressive disease (including oxygen desaturation at rest or with exercise) with failure to improve or maintain lung function while being pharmacologically treated.²⁰⁴

According to the 2012 *International Society for Heart and Lung Transplantation/United Network of Organ Sharing* (ISHLT/UNOS) International Registry, the 1-year and 5-year survival rates following lung transplantation for IPF were 84% and 48%, respectively.^{205,206} One study compared survival of patients receiving transplantation for IPF ($n = 82$) with survival of patients receiving transplantation for non-IPF diagnoses ($n = 387$).²⁰⁷ Survival estimates after transplantation for IPF were 95%, 73%, 56%, and 44% at 30 days and 1, 3, and 5 years, slightly but significantly worse than for matched non-IPF patients. Survival for double- versus single-lung transplantation for IPF patients was 81% versus 67% at 1 year and 55% versus 34% at 5 years. These findings suggest survival after lung transplantation for IPF is worse than for other indications and that survival may be improved by double-lung transplant.²⁰⁷ However, a subsequent study using the UNOS data showed no difference between patients who had single- and double-lung transplant when adjusted for baseline differences.²⁰⁸

Regular review of patients on the waiting list is required to detect complications that may affect suitability for transplantation. Unfortunately, many IPF patients die while waiting. In this context, the lung allocation score was restructured in 2005 and replaced by an algorithm based on survival probability on the waiting list and after transplantation. The aim was to decrease the number of patients who die while on the waiting list. A recent study shows that

recipient diagnoses changed, with an increase in IPF and a decrease in emphysema and cystic fibrosis.²⁰⁹

Rehabilitation

Twelve weeks of combined inpatient and home-based rehabilitation programs (respiratory muscle training and bicycle riding to the limits of the patient's tolerance) has been shown to improve the quality of life and sensation of dyspnea in patients with ILD.²¹⁰ Pulmonary rehabilitation has also been shown to improve 6MWD and fatigue.²¹¹ The beneficial effects of pulmonary rehabilitation appear to be more pronounced in patients with worse baseline functional status.²¹²

Acute Exacerbations of Idiopathic Pulmonary Fibrosis

Some patients with IPF may experience a rapid deterioration in respiratory status after a period of relative stability.^{143,213,214} This acute worsening may be related to viral or bacterial infection, aspiration, or thromboembolic event. A growing body of evidence, however, indicates that many of these acute, clinically significant episodes are of unknown etiology; these have been termed *acute exacerbations of IPF*.²¹³ The overall incidence of acute exacerbations in the IPF population remains unknown but has been suggested to range from 5% to 10%.^{213,215} An analysis of the cause of death in the placebo arm of a large randomized clinical trial, however, showed that almost half of the deaths were acute in their onset after a period of decompensation that lasted 4 weeks or less, suggesting that acute exacerbations may be more frequent than usually believed.¹⁶¹ A recent study suggested the 1- and 3-year incidences of acute exacerbation in IPF to be 14% and 21%, respectively.²¹⁶

There is no established consensus on the diagnosis of acute exacerbation of IPF. Most definitions include a combination of the following data (over < 4 weeks): (1) severe worsening of dyspnea; (2) worsening hypoxemia (i.e., a fall in arterial $PO_2 > 10$ mm Hg); (3) new radiographic opacities, usually bilateral ground-glass opacities and consolidation superimposed on the reticular/honeycomb IPF pattern (eFig. 63-11); and (4) absence of an alternative explanation, such as infection, left heart failure, or pulmonary embolism.²¹⁶⁻²¹⁹ It has been suggested that the pattern of the new ground-glass opacities may differ in the patients with acute exacerbation and that these differences might have prognostic implications.^{219,220} Although radiographs of most patients typically show ground-glass attenuation at the periphery, near areas of underlying honeycombing, some demonstrate a multifocal or diffuse pattern (see Fig. 63-11) in previously uninvolved areas. Such cases seem to have a worse prognosis than patients with only peripheral involvement.²²¹ Biopsies or autopsies of most of these patients show *diffuse alveolar damage* (DAD) superimposed on underlying UIP. Occasionally, other patterns of acute lung injury may be seen, such as organizing pneumonia and extensive fibroblastic foci.^{217,218,222} Cell profiles on BAL usually show an increase in neutrophils or in both neutrophils and lymphocytes.

The etiology and pathogenesis of the acute exacerbations remain unknown. Disordered epithelial cell integrity, acute inflammation, excessive cytokines and matrix metalloproteinases, and an antifibrinolytic alveolar milieu

are all likely involved. Increased levels of *interleukin-8* (IL-8) and α -defensin have been reported in some patients, suggesting the importance of neutrophils.²¹³ Exaggerated levels of serum ST2 protein, an orphan receptor with unknown natural ligand, have also been reported.²²³ Importantly, ST2 is preferentially expressed on *type 2 T helper* (Th2) polarized cells expressing predominantly IL-4, IL-5, or IL-10 in vitro and ex vivo, indicating a role for activated (predominantly Th2) lymphocytes.²²⁴ More recently, antibodies to annexin-1 were detected in the sera and BAL from half of patients with acute exacerbation of IPF, supporting the hypothesis that pulmonary epithelial apoptosis may be important in this pathologic event.²²⁵

Once infections and other causes of worsening have been excluded, treatment has generally consisted of enhanced immunosuppression with pulse doses of methylprednisolone (0.5 to 1 g/day). Some studies have also reported the use of additional immunosuppression with cyclophosphamide or cyclosporine, but no convincing evidence of benefit has been demonstrated. Unfortunately, no data from controlled trials have proved the efficacy of any treatment for this condition.²²⁶

FAMILIAL PULMONARY FIBROSIS

The clinical, radiographic, physiologic, and morphologic manifestations of familial IPF are indistinguishable from the sporadic form of the disease.^{47,48,227} There may be a slight male predominance, and women tend to have a more favorable prognosis.^{47,48,228,229} It is estimated that familial cases account for 0.5% to 2.2% of all patients with IIPs, with a prevalence of 1.34 cases/10⁶ population in the United Kingdom.²²⁹ In Finland, it was estimated that the prevalence for familial IPF was 5.9/million population.²³⁰ The familial form explained 3.3% to 3.7% of all Finnish cases of IPF diagnosed according to the revised American Thoracic Society/European Respiratory Society international guidelines. Geographic clustering of patients with familial IPF has been noted, suggesting a “recent founder effect,” the nonrandom genetic sampling when a population derives from a small number of individuals.^{229,230} Importantly, familial pulmonary fibrosis has been associated with multiple pathologic subsets of the IIPs: *desquamate interstitial pneumonia* (DIP),²³¹ LIP,²³² and UIP.²²⁸

The genetic basis of familial pulmonary fibrosis is unclear and probably involves several genes. Thomas and associates²²⁸ showed that mutations in the SP-C gene (*SFTPC*) are associated with familial DIP and NSIP and may cause type II cellular injury. The authors hypothesized that the presence of two different pathologic diagnoses in affected relatives sharing this mutation indicates that in this kindred, these diseases may represent pleiotropic manifestations of the same central pathogenesis.²²⁸ Multiple heterozygous mutations in *SFTPC* have been reported in association with children suffering from ILD (DIP or NSIP), including familial and sporadic cases.^{233,234} In addition, a deficiency of SP-C has been described in a small kindred suffering from a poorly defined form of interstitial pneumonitis, despite no sequence variation in *SFTPC*.²³⁵ Taken together, these findings support a model in which misfolded pro-SP-C or SP-C can cause type II alveolar cell injury that results in ILD.²³⁵ As previously mentioned, germline mutations in the essen-

tial telomerase genes, *TERT* and *TERC*, leading to abnormal telomere shortening, are the causal genetic defect in about 15% of pulmonary fibrosis families. In the Finnish families, *ELMOD2*, a functionally uncharacterized gene, was identified as a novel candidate susceptibility gene.²³⁶

Steele and colleagues⁴⁷ evaluated 111 families with two or more cases of IIP among first-degree family members having 309 affected and 360 unaffected individuals. Older age, male gender, and having ever smoked cigarettes were associated with the development of IIP. Evidence of aggregation of disease was highly significant among sibling pairs, and 20 pedigrees demonstrated vertical transmission, consistent with autosomal dominant inheritance.⁴⁷

NONSPECIFIC INTERSTITIAL PNEUMONIA

NSIP originated as a histopathologic categorization reserved for surgical lung biopsies not demonstrating a clearly identifiable pattern, notably UIP, OP, LIP, and DAD among the IIPs.²³⁷ The histopathologic pattern of NSIP is found in a wide variety of diseases of known cause (e.g., hypersensitivity pneumonitis, drug-related, *acquired immunodeficiency syndrome* [AIDS], and collagen-vascular diseases).²³⁸ Moreover, many patients diagnosed with idiopathic NSIP meet the case definition of undifferentiated connective tissue disease, suggesting that idiopathic NSIP might actually be an autoimmune disease.^{239,240} In addition, it is estimated that up to 15% to 20% of patients who present with a chronic ILD either have an occult connective tissue disease or subsequently develop a clinically overt connective tissue disease. In this particular group of patients, the initial clinical presentation may be essentially indistinguishable from that of several IIPs (especially NSIP and less commonly UIP).²⁴¹

Clinical Features

The presentation is quite similar to that of other forms of idiopathic interstitial pneumonias (see [Tables 63-7](#) and [63-8](#)). Most patients are middle-aged adults with a subacute onset of symptoms approximately 8 months before diagnosis.^{133,237,238} In contrast to IPE, two thirds of the patients are women and, unlike patients with IPE, 70% are never smokers.²³⁸ Cough and dyspnea are the main clinical manifestations. Serologic abnormalities (antinuclear antibodies and rheumatoid factor) are common. BAL findings do not discriminate between UIP and NSIP and have no prognostic value.²⁴²

Chest Imaging Studies

Chest Radiography. In patients with early NSIP, the chest radiograph may be normal. In advanced disease, bilateral reticular or hazy opacities ([eFig. 63-12](#)) are the most prominent abnormality. The lower lung lobes are more frequently involved, but an obvious apical-basal gradient, as seen in UIP, is usually absent.^{237,238}

Computed Tomography Scan. In a recent review of 61 cases of confirmed idiopathic NSIP, the parenchymal abnormalities predominantly involved the lower lungs in the craniocaudal dimension. The most common HRCT features were a reticular pattern, traction bronchiectasis, and lobar volume loss.²³⁸ Ground-glass attenuation was present in

Figure 63-26 Nonspecific interstitial pneumonia. High-resolution chest CT image shows bilateral, patchy, ground-glass opacities without evidence of subpleural honeycombing.

nearly half of the cases (Fig. 63-26). Other findings in advanced NSIP include subpleural cysts (eFig. 63-13). Compared with those of UIP, these cysts are smaller and limited in extent.²⁴³ The major CT differential diagnosis for NSIP is UIP. Favoring the diagnosis of NSIP are the following findings: homogeneous lung involvement without an obvious apical-basal gradient, extensive ground-glass opacities, a finer reticular pattern, and micronodules. Importantly, during follow-up, ground-glass opacities in NSIP patients usually do not evolve to areas of honeycombing. By contrast, progression of ground-glass opacities to honeycombing is common in UIP and indicates irreversible fibrosis.²⁴⁴

Pulmonary Function Tests

Pulmonary function testing typically shows a restrictive ventilatory defect and gas-exchange abnormalities.

Pathologic Features

The histopathologic pattern of NSIP is characterized by temporally and spatially homogeneous lung involvement. This homogeneity is a key feature in differentiating the NSIP pattern from the UIP pattern. It is characterized by varying degrees of inflammation and fibrosis, with some cases having a primarily chronic inflammatory/cellular pattern (cellular NSIP) but most cases revealing a mixed cellular-fibrotic pattern (fibrotic NSIP)^{237,238} (Figs. 63-27 and 63-28). Cellular NSIP exhibits uniform alveolar septal infiltrates of lymphocytes and plasma cells. Neutrophils, eosinophils, and histiocytes are inconspicuous. Although NSIP may have significant fibrosis, it usually appears temporally uniform; fibroblastic foci and honeycombing, if present, are rare. Fibrotic NSIP can be difficult to distinguish from UIP, and significant interobserver variability among expert histopathologists exists.¹³⁴

Differential Diagnosis

Clinically, the most common diagnosis confused with fibrotic NSIP is IPF.^{34,133,237,238} It is essential that the pathologist not use terms like “UIP” or “NSIP” unless the defined criteria are met because some degree of fibrosis and inflammation is common in many ILDs and sampling error can be

Figure 63-27 Photomicrograph of nonspecific interstitial pneumonia. Note the lymphoplasmacytic cells expanding the interstitial compartment. Alveolar macrophages are present also. (Original magnification $\times 10$.)

Figure 63-28 Photomicrograph of nonspecific interstitial pneumonia with a mixed cellular-fibrotic pattern. The alveolar walls are thickened by dense collagen and a few lymphocytes and plasma cells. The fibroblastic foci that are commonly found in the usual interstitial pneumonia pattern are not present in this lesion.

an issue, especially in small/inadequate surgical biopsies. Importantly, most biopsies showing an NSIP pattern are seen in patients who may have other conditions: an ill-defined or inadequately evaluated connective tissue disease, drug-induced ILD, chronic hypersensitivity pneumonitis, resolving acute lung injury (pneumonia or acute respiratory distress syndrome), or organizing pneumonia.^{32,150,245-249} The NSIP pattern on surgical lung biopsy should prompt the clinician to revisit the clinical data, carefully looking for these conditions.

Although it has been suggested that NSIP may represent early UIP, and while there is some histologic overlap and difficulties for pathologists in individual cases, this possibility is unlikely for several reasons. NSIP seems to develop predominantly in nonsmoking women, whereas UIP develops in smoking men.²³⁸ Early UIP (as well as advanced UIP) does not have significant inflammation but rather has scattered fibroblast foci. Finally, the patchwork pattern that is so characteristic of UIP is not seen in NSIP, and therefore, one would have to postulate that during progression, some areas of NSIP reverted to normal, whereas others evolved into fibrosis to become UIP.³⁶

Clinical Course and Outcome

Several retrospective studies indicate the survival rate of patients with idiopathic NSIP is significantly higher than those with UIP.^{133,134,237,238,250} This difference persists even after adjusting for age, gender, smoking history, and physiologic variables. Those patients with a purely cellular pattern on biopsy demonstrate the longest survival, indicating that prognosis depends primarily on the extent of fibrosis.^{150,238} In those patients who show an NSIP pattern in one lobe and a UIP pattern in another, the survival is similar to those with UIP. In NSIP, corticosteroids combined with azathioprine may be more effective than corticosteroids alone.

RESPIRATORY BRONCHIOLITIS–ASSOCIATED INTERSTITIAL LUNG DISEASE/DESQUAMATIVE INTERSTITIAL PNEUMONIA

Respiratory bronchiolitis–associated interstitial lung disease (RB-ILD) and DIP are related and, in some cases, inseparable conditions because most cases appear to represent different stages of the same process.^{251–253} These diseases represent a distinct clinical syndrome found in current heavy smokers. The term *respiratory bronchiolitis–associated interstitial lung disease* is more anatomically accurate because it conveys important pathogenic implications compared with the older term “desquamative interstitial pneumonia.” Both (primarily RB-ILD) account for 15% to 20% of biopsied patients with IIPs (see [Tables 63-7](#) and [63-8](#)).^{254,255} Importantly, respiratory bronchiolitis is an accurate histologic marker of cigarette smoking, and it may be found many years after smoking ceases.²⁵⁶ The level of cytoplasmic pigmentation of macrophages and the presence of peribronchial fibrosis correlate with the pack-year smoking history.²⁵⁶ Moreover, it was recently reported that those with significant lifetime secondhand smoke exposure, especially in the previous 12 months, have significant increases in ground-glass opacities on HRCT, suggesting an early or subclinical respiratory bronchiolitis/DIP.²⁵⁷ Furthermore, RB/DIP-like histologic changes (1) are exceedingly common in PLCH, (2) may be sufficiently severe to cause the appearance of ground-glass opacities on HRCT, and (3) correlate with the cumulative exposure to cigarettes smoked.²⁵⁸ Although cigarette smoking is considered the main cause of RB-ILD/DIP, genetic abnormalities of surfactant function, specifically mutations in the genes coding for SP-B, SP-C, ABCA3, account for an increasing number of ILDs including DIP.^{259,260} In addition, DIP can be observed in various occupational or drug^{38,39,255} exposures.^{38,255,261}

Clinical Features

RB-ILD and DIP primarily afflict cigarette smokers between the third and the sixth decades of life.^{38,39,255} There is a male preponderance, with men affected nearly twice as often as women. Patients with either RB-ILD or DIP commonly present with insidious exertional dyspnea and persistent nonproductive cough. Less frequently, patients with DIP experience fatigue and weight loss. Coarse, bibasilar end-inspiratory crepitations are frequent findings on physical examination, whereas finger clubbing is uncommon.

Figure 63-29 Desquamative interstitial pneumonia. Axial high-resolution CT shows patchy, multifocal ground-glass opacity associated with areas of interlobular septal thickening and intralobular interstitial thickening. (Courtesy Michael Gotway, MD.)

Chest Imaging Studies

Chest Radiography. The chest radiograph is insensitive for detection of RB-ILD and is often normal. Sometimes, bronchial wall thickening or reticular opacities can be seen ([eFig. 63-14](#)). Chest radiographs of DIP ([eFig. 63-15](#)) are nonspecific and usually reveal bilateral ground-glass opacities. Middle and lower lung field involvement with normal-appearing lung volumes predominates.^{38,39,255} Air bronchograms can be found when this process surrounds the airways. The honeycomb pattern is rare.

Computed Tomography Scan. The key HRCT features of RB-ILD include central bronchial wall thickening proximal to segmental bronchi, peripheral bronchial wall thickening distal to segmental bronchi, centrilobular nodules ([eFig. 63-16](#)), and areas of ground-glass opacity.^{253,262,263} ([Fig. 63-29](#)). Ground-glass opacifications may be diffuse or patchy, without basal or peripheral predominance.^{253,263,264} The predominant abnormality in DIP ([eFig. 63-17](#)) is the bilateral, moderately symmetrical, peripheral, and predominantly basal ground-glass attenuation. Tiny thin-walled cysts ([eFig. 63-18](#)) are noted within the ground-glass opacities in 30% to 60% of cases.^{265–267} A honeycombing pattern is rarely found.^{38,263,265,267}

There is occasional overlap in appearances between RB-ILD and DIP, although the ground-glass attenuation of DIP is usually more extensive, and nodules are infrequent or absent.²⁶⁸

Bronchoalveolar Lavage

BAL fluid in patients with RB-ILD/DIP is characterized by mild to moderate increases in total cell numbers, moderate to marked eosinophilia (a feature that in the absence of biopsy might raise the consideration of chronic eosinophilic pneumonia), and moderate neutrophilia.^{265,268}

Pulmonary Function Tests

Pulmonary function testing may be normal but usually shows mild to moderate restriction, normal or slightly reduced diffusing capacity, and mild hypoxemia.^{38,39,268} A mixed obstructive-restrictive pattern is common, although there may be an isolated increase in residual volume.

Figure 63-30 Photomicrograph of respiratory bronchiolitis. There is an ectatic small airway (circle), with thickened walls and extension of the bronchiolar metaplastic epithelium into the immediately surrounding alveoli. Intraluminal macrophages are also present within the peribronchiolar alveolar spaces.

Figure 63-31 Photomicrograph of desquamative interstitial pneumonia. Characteristic dense collections of macrophages are seen filling alveolar lumens. (Original magnification $\times 100$.)

Pathologic Features

The cardinal feature of RB-ILD is the accumulation of alveolar macrophages within the bronchioles, including the terminal and respiratory bronchioles, variably extending into alveolar ducts and alveoli.^{37,254,256,269} In contrast to RB-ILD, DIP shows a much more widespread and uniform filling of all alveoli, although in any given biopsy one can find low-power fields showing only RB-ILD type changes and others typical of DIP. This histologic observation supports the close association of RB-ILD and DIP. Macrophages are characterized by glassy eosinophilic cytoplasm, usually with brown and finely granular pigmentation (representing constituents of cigarette smoke).^{32,254,268,269} There is often a chronic inflammatory cell infiltrate in bronchiolar and surrounding alveolar walls. The changes are patchy at low magnification and have a distinctly bronchiolocentric distribution without the associated diffuse involvement and interstitial pneumonia necessary for a diagnosis of DIP (Fig. 63-30).²⁵⁴

Bedrossian and coworkers²⁷⁰ coined the term *DIP-like reaction* to identify prominent intra-alveolar macrophage accumulation around space-occupying pulmonary lesions. This DIP-like reaction can be seen in a number of other processes, including pulmonary Langerhans cell histiocytosis, drug reactions (e.g., amiodarone), chronic alveolar hemorrhage, eosinophilic pneumonia, pneumoconioses (e.g., talcosis, hard-metal disease, asbestosis), obstructive pneumonias, and exogenous lipid pneumonia.^{8,271} In these cases, however, the DIP-like reaction is usually focal, without the uniform involvement of lung parenchyma seen in true cases of RB-ILD/DIP.

As mentioned, the histologic hallmark of DIP is the uniform filling of the alveolar spaces by cohesive clusters of numerous pigmented alveolar macrophages, including occasional multinucleated cells, eosinophils, and lymphocytes.^{254,271} Alveolar septa are thickened by a sparse inflammatory infiltrate and lined by uniform hyperplastic type II pneumocytes. Peribronchiolar lymphoid hyperplasia is seen in the majority of cases (Fig. 63-31).^{254,271}

The majority of DIP cases show a difference in the degree of pathologic change from one lobule to the next in a given biopsy specimen. Some degree of architectural destruction is usually observed. Akira and colleagues²⁶⁷ have pointed out the presence of dilated alveolar ducts and bronchioles and/or pulmonary cysts, which corresponded to cystic spaces on HRCT.²⁶⁵

Clinical Course and Outcome

Because there has not been a longitudinal study of a large group of subjects, the clinical course and prognosis of patients with RB-ILD are unknown. Most studies suggest a favorable response to smoking cessation and the use of corticosteroids, with documented improvement in lung function and chest radiographs²⁶⁹; few deaths secondary to progressive lung disease have been reported.³⁹

Patients with the DIP stage of this process also have a good prognosis. Carrington and associates²⁶¹ reported a 28% mortality after an average survival of 12 years. Other studies have shown similar results, but additional study of a larger number of subjects is necessary.^{38,263,267,269} In another study, symptomatic improvement (i.e., improved cough, dyspnea, or both) with prednisone treatment was noted in 24% of patients with DIP and 55% of patients with RB-ILD.³⁸ Objective improvement with prednisone treatment, as evidenced by improvement in pulmonary function measurements or parenchymal opacities seen on chest radiography or CT scans, was noted in 33% of patients with DIP and 64% of patients with RB-ILD.³⁸ Unfortunately, these positive responses tended to be transient in half of the patients with tapering and discontinuation of prednisone treatment. Patients can regress back to the baseline status even in the absence of smoking.³⁸

Nevertheless, because smoking plays a major role in the pathogenesis, smoking cessation is always indicated in these patients. In a recent study, both clinical symptoms and DL_{CO} improved significantly following smoking cessation, as did ground-glass opacities and centrilobular nodules seen on the initial HRCT examination.²⁷² Corticosteroids

may be required in refractory or recurrent cases but should not be instituted in the absence of smoking cessation.

ACUTE INTERSTITIAL PNEUMONIA

AIP is a rare, fulminant form of lung injury that presents acutely (days to weeks from onset of symptoms), usually in a previously healthy individual.²⁷³⁻²⁷⁵ AIP likely represents a subset of cases of idiopathic acute respiratory distress syndrome and is what Hamman and Rich²⁷⁶ described and termed “acute diffuse interstitial fibrosis” (see [Tables 63-7](#) and [63-8](#)).

Clinical Features

Most patients are older than 40 (mean age, 50 years; range, 7 to 83 years).^{273,274} Men and women are equally affected, and cigarette smoking does not seem to increase the risk for development of AIP. A prodromal illness, usually lasting 7 to 14 days before presentation, is common. The clinical signs and symptoms include fever, cough, and shortness of breath. Routine laboratory studies are nonspecific and generally not helpful.

Chest Imaging Studies

Chest Radiography. Diffuse, bilateral, air space opacification is seen on chest radiograph ([eFig. 63-19](#)).²⁷⁷⁻²⁷⁹

Computed Tomography Scan. The typical HRCT features of AIP are bilateral, multifocal or diffuse areas of ground-glass opacity and consolidation, usually without pleural effusion ([eFig. 63-20](#)).^{50,51,60,277} A predominantly subpleural distribution may be seen. These radiographic findings are similar to those seen in the acute respiratory distress syndrome; however, patients with AIP are more likely to have a symmetrical, bilateral distribution with a lower lobe predominance.²⁸⁰ In the early phase of AIP, ground-glass opacities and less extensive areas of consolidation are the dominant CT pattern, reflecting the presence of alveolar septal edema and hyaline membranes.⁵¹ During the organizing phase of the disease, HRCT findings consistent with evolving fibrosis are often present, including traction bronchiectasis, reticular opacities, and architectural distortion.²⁸¹ In this phase, consolidations resulting from intra-alveolar fibrosis may also be present. Mild honeycombing, usually involving less than 10% of the lung, may be seen on CT.²⁷⁷

Pulmonary Function Tests

Most patients have moderate to severe hypoxemia and develop respiratory failure.²⁷³⁻²⁷⁵

Pathologic Features

A surgical lung biopsy is required to confirm the diagnosis of AIP.^{32,254,273} The histopathologic pattern seen in AIP is DAD, which can be categorized into an early exudative phase, an organizing phase, and a chronic phase, depending on the timing of the biopsy in relation to the lung insult. DAD develops after an acute injury to the alveolar capillary basement membranes.^{273,275} DAD is common and also seen in immunosuppressed patients who have received cytotoxic drugs or who have developed diffuse infectious pneumonias, as well as in a number of other settings.²⁸²⁻²⁸⁴

Figure 63-32 Photomicrograph of acute interstitial pneumonia shows diffuse alveolar damage. Note the hyaline membranes (arrows) within alveolar spaces and edema and inflammatory cell infiltration of the alveolar wall. (Original magnification $\times 10$.)

After the endothelial-epithelial injury, there is leakage of serum proteins and red blood cells into the alveolar spaces. The alveolar epithelium becomes necrotic and is sloughed, and the interstitium becomes edematous. Hyaline membranes, recognized as eosinophilic debris and consisting of necrotic epithelial cells, protein, and fibrin, form within alveolar spaces ([Fig. 63-32](#)). In the reparative or organizing stage of DAD, there is proliferation and hyperplasia of the alveolar type II epithelial cells, often showing nuclear enlargement and prominent nucleoli. Extensive fibroblast proliferation is a dominant finding in the organizing phase; proliferating fibroblasts and myofibroblasts within a myxoid basophilic matrix may be seen within alveolar septa or in the alveoli (resembling organizing pneumonia).²⁵⁴ Fibrin thrombi are often present. In some cases, these pathologic changes may resolve, but in others, perhaps due to protracted or repeated parenchymal injury, irreversible fibrosis and honeycomb lung result.

Clinical Course and Outcome

Treatment is largely supportive and consists of mechanical ventilation and oxygen supplementation.^{273,274,279,282} Corticosteroids seem to be effective in the early phase of disease. According to most studies, the mortality from AIP appears to be high (>50%), with the majority of patients dying within 3 months of presentation.^{273-275,279} Most survivors of AIP experienced recurrences and chronic, progressive ILD.²⁷⁹ However, a lower hospital mortality (12.5%) with no evidence of either recurrent or progressive disease has been also described.²⁸⁵

CRYPTOGENIC ORGANIZING PNEUMONIA

Organizing pneumonia (OP) can be cryptogenic (i.e., COP) or result from various forms of lung injuries (e.g., postinfectious, drug related, connective tissue disease related, post-transplant, hypersensitivity pneumonitis, radiation, or aspiration of particulate matter). COP is a specific clinicopathologic syndrome characterized by a “pneumonia-like” illness, with excessive proliferation of granulation tissue inside the alveolar spaces associated with chronic inflammation in the surrounding alveoli.^{32,33,40} The pathologic process may also involve the small airways (*bronchiolitis*

obliterans with organizing pneumonia [BOOP]) (see Tables 63-7 and 63-8). There are no major differences in clinical features of COP and secondary OP.²⁸⁶⁻²⁸⁸ OP may also be seen accompanying other histopathologic patterns (e.g., UIP). The diagnosis of COP is reserved for isolated OP in patients without an identifiable associated disease. The term *idiopathic BOOP* historically encompassed COP but is no longer recommended for this idiopathic condition.³²

Clinical Features

The incidence of COP is similar in both men and women.²⁸⁷ The mean age at presentation is about 50 to 55 (range, 21 to 80). Patients with COP are frequently specific about the timing of their disease onset. This is because the disease onset is recent (usually < 2 months) and is often dramatic, with the development of a flulike illness characterized by cough, mild dyspnea, fever, malaise, fatigue, and weight loss. Physical examination usually discloses focal sparse crackles but may be almost normal. Finger clubbing is rare.

Routine laboratory studies are nonspecific. A leukocytosis without increase in eosinophils is seen in approximately half the patients. The initial erythrocyte sedimentation rate is frequently elevated in patients with COP.

Chest Imaging Studies

Chest Radiography. The radiographic manifestations are distinctive, usually including unilateral or bilateral patchy consolidations that resemble pneumonic opacities in the presence of normal lung volumes (eFig. 63-21).^{50,289} A peripheral distribution of the opacities, similar to that thought to be “virtually pathognomonic” for chronic eosinophilic pneumonia, is commonly seen in COP.^{288,290,291} Irregular linear or nodular interstitial opacities are rarely present as the only radiographic manifestation (eFig. 63-22).²⁹² Honeycombing is rare and is seen only as a late manifestation in the few patients with progressive disease. Other radiographic abnormalities, such as pleural effusion, pleural thickening, hyperinflation, and cavities, are uncommon.

Computed Tomography Scan. CT scans of the lung reveal patchy air space consolidation, small nodular opacities, and bronchial wall thickening and dilation, most frequently in the periphery of the lung and often in the lower lung zones^{55,289,290,292} (Fig. 63-33, Video 63-2). Frequently, the CT findings are far more extensive than are expected by review of the chest radiograph. These opacities tend to migrate and decrease in size, even without treatment (eFig. 63-23). The CT finding of consolidation is associated with partial or complete resolution, whereas reticular opacities are associated with persistent or progressive disease (eFig. 63-24).²⁹³ Sometimes, COP shows unique findings such as the reversed halo sign (eFig. 63-25), which is defined as central ground-glass opacity surrounded by more dense air space consolidation of crescentic and ring shapes. This sign is seen in around 20% of patients with COP.²⁹⁴ The presence of enlarged nodes is less common in COP than in the other IIPs.²⁹⁵

Focal OP has been described as a discrete form of COP and presents as an isolated focal lesion on chest imaging.²⁹⁶⁻²⁹⁸ Many of these patients are asymptomatic,

Figure 63-33 Cryptogenic organizing pneumonia. Axial CT shows areas of peripheral (arrows) and peribronchovascular (arrowheads) consolidation. (Courtesy Michael Gotway, MD.)

and the lesion is discovered by chest radiograph or CT. It may be suspected to be a putative lung cancer because most patients have a smoking history and are middle-aged or older.²⁹⁸

Pulmonary Function Tests

Pulmonary function is usually impaired, with a restrictive defect being most common, although an obstructive defect (FEV₁/FVC ratio < 70%) is found in almost one fifth of subjects with COP, mostly in current or former smokers.^{287,299} Gas-exchange abnormalities are extremely common, with resting and exercise arterial hypoxemia. The DL_{CO} is reduced (<80% of predicted) in three fourths of patients.

Bronchoalveolar Lavage

An increase in lymphocytes (20% to 40%), neutrophils (10%), and eosinophils (5%), with the level of lymphocytes higher than that of eosinophils, is the most common pattern at differential cell count.²⁸⁷ BAL lymphocytes are activated and the CD4/CD8 ratio is usually decreased. An increase of plasma cells and/or mast cells may also be seen.

Pathologic Features

The diagnosis of COP depends on both the clinical setting and the finding of the characteristic pathologic features. Intraluminal fibroblastic buds, also called Masson bodies, seen in respiratory bronchioles, alveolar ducts, and alveoli are the most prominent feature.^{32,250,300} Other pathologic features include foamy cells in the alveolar spaces, prominent type II cell hyperplasia, interstitial infiltrates, and fibrinous exudates.

OP is recognized by the appearance in the small airways of intraluminal collections of proliferating fibroblasts and myofibroblasts in a mucopolysaccharide-rich matrix. It is most prominent in the alveolar ducts but extends distally to the alveolar lumina and proximally to the bronchioles (Fig. 63-34). These Masson bodies may also extend from one alveolus to the next through the interalveolar pores, giving a characteristic “butterfly pattern.”²⁸⁷ OP can also show an interstitial lymphoplasmacytic infiltrate and hyperplasia of the type II epithelial cells. The organizing process, which may extend into the bronchioles, produces an intraluminal polypoid bronchiolitis obliterans (Fig. 63-35). OP represents a common reparative response to injury seen in a

Figure 63-34 Photomicrograph indicates organizing pneumonia. Immature connective tissue and proliferating fibroblasts appearing blue/green (pentachrome stain) (also called Masson bodies) are present in alveolar ducts and alveolar spaces, and there is an interstitial infiltrate consisting of mononuclear cells. (Original magnification $\times 40$.)

Figure 63-35 Photomicrograph of organizing pneumonia. There is a typical inflammatory polyp extending into the lumen of a terminal bronchiole (arrows). (Original magnification $\times 40$.)

variety of ILDs, infectious pneumonias, and many other processes. If the injury is unresponsive to treatment, progression to irreversible fibrosis and a honeycombed lung can result.

Clinical Course and Outcome

Corticosteroid therapy results in complete clinical, radiologic (eFig. 63-26), and physiologic recovery in two thirds of patients.²⁸⁷ One third demonstrates recurrent or persistent disease. Secondary OP (e.g., OP associated with connective tissue diseases), is less likely to respond to corticosteroids. In general, clinical improvement is rapid, within several days or a few weeks. Occasionally, recovery is quite dramatic. Patients can relapse when the corticosteroids are withdrawn, usually within 1 to 3 months. Most relapsed patients will improve when retreated with corticosteroids.³⁰¹ It has been suggested that COP may also respond to macrolide therapy, but studies are scanty.³⁰² A few patients may improve spontaneously over 3 to 6 months.^{287,303} A seasonal (early spring) presentation of COP with relapse every year at the same period has been reported.³⁰⁴ Few of the patients with COP die as a result of this illness, but those prone to develop a rapidly progressive

fatal form of OP have a clinical course similar to AIP.³⁰⁵ In such patients, the diagnosis is usually delayed or missed.

The majority of cases of focal OP are cryptogenic, do not recur after surgical resection, and do not require corticosteroid therapy.^{298,306,307}

IDIOPATHIC LYMPHOCYTIC INTERSTITIAL PNEUMONIA

LIP is an uncommon pathologic pattern characterized by the presence of widespread, monotonous sheets of lymphocytic infiltration in the interstitium of the lung.³⁰⁸⁻³¹⁰ Idiopathic LIP is rare and, in addition to being differentiated from other IIPs, it must be distinguished from other lymphocytic infiltrations in the lung, notably lymphomas, and ILDs associated with prominent lymphoid infiltrates such as collagen vascular diseases (especially Sjögren syndrome); dysproteinemia; drug reactions; hypersensitivity pneumonitis; immunodeficiency syndromes (e.g., HIV, combined variable immunodeficiency); and hematopoietic stem cell transplantation. The LIP pattern is far more common as a secondary disease in association with systemic disorders and most of the prior reports on LIP included such cases (Table 63-10).³¹¹⁻³¹⁴

Clinical Features

Patients most commonly present with progressive dyspnea and cough, although they may also have weight loss, pleuritic pain, arthralgias, and fever.³⁰⁸⁻³¹⁰ Bibasilar crackles are present on chest auscultation in most patients. Digital clubbing is usually absent and cyanosis is a rare physical finding. Extrapulmonary findings related to the underlying disease process may be present.

Figure 63-36 Lymphocytic interstitial pneumonia. High-resolution CT image shows diffuse cysts.

Figure 63-37 Photomicrograph of lymphocytic interstitial pneumonia. A diffuse lymphoid infiltrate extends through the pulmonary interstitium. (Original magnification $\times 10$.)

Chest Imaging Studies

Chest Radiography. The chest radiograph is nonspecific, with reticular opacities (eFig. 63-27) being the most frequent abnormality. A mixed alveolar-interstitial pattern appears as the disease progresses because of the coalescence of the opacities. Cysts, honeycombing, and pulmonary hypertension are also late manifestations.³¹⁵ Pleural effusions are infrequent and suggest a complicating lymphoma.

Computed Tomography Scan. The main parenchymal abnormalities on the initial CT scan consisted of ground-glass attenuation (eFig. 63-28), thickening of interlobular septa, centrilobular nodules (eFig. 63-29), thin-walled perivascular cysts, and air space consolidation (see eFig. 63-28)^{55,313} (Fig. 63-36). In contrast to the subpleural, lower lung cystic changes in UIP, the cysts of LIP are usually within the lung parenchyma throughout the mid lung zones and presumably result from air trapping due to peribronchiolar cellular infiltration.³¹³⁻³¹⁵ The cysts may be seen in up to 80% of patients and are typically few in number, measuring less than 3 cm in diameter. On follow-up CT, most patients improve, although several show increased extent of disease (eFig. 63-30). With the exception of cysts, the parenchymal opacities are reversible.³¹⁴ New cysts develop in a few patients; these develop mainly in areas with centrilobular nodules on initial CT. Honeycombing has been seen on follow-up CT in several patients in areas of previous air space consolidation on the initial CT.³¹⁴

Pulmonary Function Tests

A restrictive defect including reduced FVC, elevated FEV₁/FVC, and reduced TLC is commonly seen and is often associated with a reduction in the DL_{CO} and arterial hypoxemia.³⁰⁸⁻³¹⁰

Bronchoalveolar Lavage

A striking T-cell lymphocytosis is seen on BAL.³⁰⁹

Pathologic Features

Surgical lung biopsy is generally required for the diagnosis. The lymphocytic infiltration is usually extensive and severe, involving the alveolar septa and peribronchiolar and perivascular interstitium^{32,33,308} (Fig. 63-37). Reactive lymphoid follicles are often present and distributed along the peribronchiolar regions. The lymphocytes are polytypic (both B and T cells may be found), distinguishing them from the monotypic lymphocytic infiltrates characteristic of pulmonary lymphoma. The number of plasma cells and macrophages is also increased in these infiltrates.

LIP is distinguished from DIP and NSIP by the marked density of the lymphoid infiltrate in the former, although there are no precise criteria.^{32,33,308} Other features include the interstitial accumulation of macrophages, noncaseating granulomas, perivascular amyloid deposits, and germinal lymphoid centers.

LIP is distinguished from DIP and NSIP by the marked density of the lymphoid infiltrate in the former, although there are no precise criteria.^{32,33,308} Other features include the interstitial accumulation of macrophages, noncaseating granulomas, perivascular amyloid deposits, and germinal lymphoid centers.

Clinical Course and Outcome

The clinical course of idiopathic LIP is unknown. In cases in which LIP is associated with another disease, the underlying disease largely determines the outcome. In many case reports, marked improvement or complete resolution has followed corticosteroid therapy.³⁰⁹⁻³¹¹ However, patients can progress to pulmonary fibrosis, cor pulmonale, and death despite therapy. Infection is a common complication, especially in those with an associated dysproteinemia.³⁰⁹⁻³¹² Progression to pulmonary or systemic lymphoma appears to be rare and it is likely that, in this group of patients, malignant lymphoma was present from the outset.^{310,312,316,317}

IDIOPATHIC PLEUROPARENCHYMAL FIBROELASTOSIS

Idiopathic pleuroparenchymal fibroelastosis is another rare form of IIP and is characterized by a fibrotic process involving the pleura and subjacent parenchyma with a predominantly upper lobe distribution.³¹⁸⁻³²⁰ Patients with idiopathic pleuroparenchymal fibroelastosis present with exertional dyspnea with or without cough. A history of repeated lower respiratory tract infections may be elicited in some of these patients.³²⁰

CT features consist of bilateral irregular pleuroparenchymal thickening resulting from the fibrotic process and is more prominent in the upper and middle zones (eFig. 63-31).^{318,320,321} Histopathologic features include intra-alveolar fibrosis with septal elastosis.³¹⁸⁻³²⁰

The majority of patients with idiopathic pleuroparenchymal fibroelastosis experience disease progression. In a report by Reddy and colleagues,³²⁰ 5 of 10 patients died within 2 years of diagnosis. Prednisone treatment even with additional immunosuppressive therapy did not appear to have a beneficial effect.

Key Points

- Interstitial lung diseases include inflammatory and fibrotic diseases that ultimately disrupt the alveolar-capillary interface, leading to hypoxemia.
- Interstitial lung diseases arise in many diverse clinical settings, including connective tissue disease; occupational, environmental and drug exposures; and primary pulmonary disorders.
- In some patients, correlation of the clinical context (detailed history and examination along with relevant laboratory results) and radiologic features can establish the likely diagnosis.
- Ultimately, histopathologic examination of lung tissue (more often by surgical lung biopsy than bronchoscopic biopsy) may be necessary to confirm a specific diagnosis in interstitial lung disease.
- Idiopathic interstitial pneumonias are a subgroup of interstitial lung diseases of unknown etiology and are associated with variable radiologic features, response to therapy, and clinical course.
- Idiopathic pulmonary fibrosis is the most common of the interstitial lung diseases and is progressive, irreversible, and usually fatal with a portion of these deaths attributed to the phenomenon of “acute exacerbation.”
- The U.S. Federal Drug Administration has approved pirfenidone and nintedanib for the treatment of idiopathic pulmonary fibrosis.
- *Nonspecific interstitial pneumonia* (NSIP) is characterized by diffuse, temporally, and geographically homogeneous cellular infiltrates (cellular NSIP) or fibrosis (fibrotic NSIP). NSIP is often associated with collagen vascular diseases, drug-induced disease, and hypersensitivity pneumonitis among others. In general, patients with NSIP (especially cellular NSIP) fare better than those with idiopathic pulmonary fibrosis.

- Respiratory bronchiolitis-associated interstitial lung disease and desquamative interstitial pneumonia are smoking-related in most patients.

eFIGURE IMAGE GALLERY

eFigure 63-1 CT of “early” usual interstitial pneumonia/idiopathic pulmonary fibrosis. Axial chest CT through the lung bases shows subpleural reticulation and architectural distortion with areas of traction bronchiectasis, but no discrete honeycombing is visualized. (Courtesy Michael Gotway, MD.)

eFigure 63-2 CT of advanced IPF. Axial chest CT through the lung bases shows extensive basal and subpleural honeycombing. (Courtesy Michael Gotway, MD.)

eFigure 63-3 Value of coronal CT for demonstrating the basal distribution of pulmonary findings in interstitial pneumonia/idiopathic pulmonary fibrosis. Coronal chest CT shows subpleural reticulation and basal predominant honeycombing. This single image captures the basal predominant nature of the high-resolution CT (HRCT) findings in patients with idiopathic pulmonary fibrosis. (Courtesy Michael Gotway, MD.)

eFigure 63-4 Honeycombing on HRCT in usual interstitial pneumonia/idiopathic pulmonary fibrosis. Axial prone chest CT through the lung bases shows extensive subpleural cystic change consistent with honeycomb lung. Note how the cyst walls are visible, are mildly thickened (measuring 1 to 2 mm), and share walls with one another. (Courtesy Michael Gotway, MD.)

eFigure 63-5 CT of combined pulmonary fibrosis and emphysema. Axial chest CT through the upper lungs (**A**) and lung bases (**B**) shows centrilobular (*single arrowhead*) and paraseptal (*double arrowheads*) emphysema, with basal predominant reticulation, architectural distortion, and honeycombing (*arrow*), the latter consistent with interstitial pneumonia/idiopathic pulmonary fibrosis. (See [Video 63-1](#) for another example from a different patient.) (Courtesy Michael Gotway, MD.)

eFigure 63-6 CT of chronic hypersensitivity pneumonitis. Axial chest CT performed through the mid (**A**) and lower lungs (**B**) and extreme bases (**C**) shows relative basal sparing of pulmonary abnormalities compared with more cranial imaging levels, typical of hypersensitivity pneumonitis; this relative basal sparing is a useful feature for differentiating hypersensitivity pneumonitis from idiopathic pulmonary fibrosis. Other features of hypersensitivity pneumonitis are also evident, including ground-glass opacity (*single arrowhead*) and areas of lobular air trapping (*double arrowheads*), the latter consistent with small airway obstruction. Architectural distortion is present, consistent with the presence of fibrosis in this patient with chronic hypersensitivity pneumonitis. (Courtesy Michael Gotway, MD.)

eFigure 63-7 PET-CT of idiopathic pulmonary fibrosis. Axial chest CT (**A**) shows basal, subpleural reticulation, traction bronchiectasis, and trace honeycombing representing idiopathic pulmonary fibrosis. Fused image from PET-CT (**B**) shows increased tracer utilization within the areas of fibrotic lung disease. Tracer uptake anteriorly represents cardiac activity. (Courtesy Michael Gotway, MD.)

eFigure 63-8 CT and PET-CT in idiopathic pulmonary fibrosis with coincident lung carcinoma. Axial chest CT (**A**) shows basal, subpleural reticulation and traction bronchiectasis representing idiopathic pulmonary fibrosis. A subpleural nodule (arrow, **A**) is present, representing lung carcinoma. Fused image from PET-CT (**B**) shows increased tracer utilization within the nodule (arrow, **B**), as well as faint tracer uptake within the areas of fibrotic lung disease. (Courtesy Michael Gotway, MD.)

eFigure 63-9 Progression of fibrosis on chest radiography in idiopathic pulmonary fibrosis. Serial chest radiographs performed in 2004 (**A**), 2008 (**B**), and 2012 (**C**) show progressive development of linear and reticular abnormalities predominating in the mid and lower lungs, consistent with progressive fibrotic changes in a patient with idiopathic pulmonary fibrosis. (Courtesy Michael Gotway, MD.)

eFigure 63-10 Honeycombing on chest radiography in idiopathic pulmonary fibrosis. Frontal (A) and lateral (B) chest radiographs show peripheral predominant reticulation and linear opacities consistent with fibrotic changes in a patient with idiopathic pulmonary fibrosis. Note the cystic appearance best seen in the posterior and inferior lungs on the lateral chest radiograph (B); these cystic spaces represent honeycombing. (Courtesy Michael Gotway, MD.)

eFigure 63-11 Chest radiography and CT of accelerated interstitial pneumonia in idiopathic pulmonary fibrosis. Frontal (A) and lateral (B) chest radiographs show multifocal, bilateral reticular abnormalities, with cystic change most evident in the posterior and inferior lung bases on the lateral radiograph (B), consistent with fibrotic changes in a patient with idiopathic pulmonary fibrosis. In addition to these findings, more widespread areas of increased attenuation as well as a generalized nodular appearance are evident. Axial chest CT images in the upper (C), mid (D), and lower (E) lungs, as well as the extreme lung bases (F), show peripheral predominant fibrotic changes consistent with idiopathic pulmonary fibrosis. However, extensive areas of ground-glass opacity are evident, particularly in the left mid (D) and lower (E) lungs, and are consistent with an acute lung injury pattern and not fibrosis. (Courtesy Michael Gotway, MD.)

eFigure 63-12 Chest radiography of nonspecific interstitial pneumonia. Frontal chest radiograph shows patchy, bilateral areas of increased attenuation associated with faint areas of underlying reticulation; lung volumes are relatively preserved. (Courtesy Michael Gotway, MD.)

eFigure 63-13 CT showing subpleural cystic change in nonspecific interstitial pneumonia. PREVENTION**INTRODUCTION**

Hypersensitivity pneumonitis (HP), also known as extrinsic allergic alveolitis, constitutes a spectrum of granulomatous, interstitial, bronchiolar, and alveolar-filling lung diseases resulting from repeated inhalation of and sensitization to a wide variety of organic aerosols and low-molecular-weight chemical antigens. Increasing recognition of the ubiquity of environmental antigen exposures and improved diagnostic tools have led to identification of cases and outbreaks of HP in a wide variety of occupational and environmental settings. The disease is a lymphocyte-driven process that manifests in a range of clinical phenotypes.

HP remains a diagnostic challenge because of the spectrum of clinical findings and the lack of a simple gold standard for diagnosis. The diagnosis depends on a strong clinical index of suspicion, a careful exposure history, and the integration of imaging and histopathologic findings. By themselves, these findings are nonspecific and may mimic a variety of other chest illnesses. HP is usually treatable if the exposure is recognized and antigen is effectively avoided. Unrecognized or untreated illness may lead to permanent airway reactivity, emphysema, and interstitial fibrosis.

ETIOLOGY

The list of specific agents that cause HP is extensive, and new exposure circumstances and disease entities continue to be described. The distinctive and often colorful disease names for HP can be organized more simply into three major categories of causal antigens: microbial agents, animal proteins, and low-molecular-weight chemicals (Table 64-1). There are also increasing numbers of pharmacologic agents that have been shown to cause hypersensitivity reactions in the lung, but the mechanisms and nature of these drug reactions are distinct from those of classic HP and are covered elsewhere under the subject of drug-induced lung diseases (see Chapter 71).

MICROBIAL AGENTS

Microbial organisms, including bacteria and fungi, are common in indoor environments. Warm, moist environments often provide ideal circumstances for the amplification and proliferation of microbial antigens that, if aerosolized and inhaled, can cause lung disease in a susceptible and previously sensitized host.

Bacteria have adapted to a wide variety of ecologic habitats and segregate under different physical and chemical conditions in indoor and outdoor environments. Thermophilic actinomycetes in hay are associated causally with the prototypical example of HP, *farmer's lung disease* (FLD), first described in 1932. These bacteria are ubiquitous in the environment and thrive in 50°C to 55°C temperatures and moist conditions. They secrete enzymes that facilitate decay of vegetable matter, but that can also cause immunologic lung reactions when inhaled. In addition to hay, thermophilic bacteria can be found in sugar cane (bagassosis) and mushroom compost (mushroom worker's lung) and can contaminate ventilation and humidification systems (humidifier lung) where temperatures can reach 60°C and stagnant water is present. Indoor bacteria that thrive at lower temperatures also can cause HP, and case reports have been associated with *Bacillus* spp. in contaminated wood dust, *Klebsiella* spp. in humidifiers, and *Epicoccum* spp. associated with moisture from a basement shower. Nontuberculous mycobacteria are an increasingly recognized cause of HP, mainly from workplace and recreational exposure to hot tub aerosols, but also from exposure to nontuberculous mycobacteria contaminants in shower heads.¹ There have also been outbreaks of HP from exposure to indoor swimming pools, termed "lifeguard lung," and to metalworking fluid aerosols contaminated with nontuberculous mycobacterial antigens.²⁻⁵

Exposure to fungal antigens is implicated in some HP cases.⁶ Components of fungi capable of becoming airborne include spores, mycelial fragments, metabolites and partially degraded substrates, and toxins. Among the interior sites for mold growth are garbage containers, food storage

Table 64-1 Etiologic Categories of Hypersensitivity Pneumonitis, with Examples**MICROBIAL AGENTS****Bacteria**

Examples: *Thermophilics*, *Bacillus subtilis*, *Klebsiella*, *Epicoccum nigrum*, nontuberculous mycobacteria

Fungi

Examples: *Aspergillus*, *Penicillium*, *Cladosporium*, *Trichosporon*, *Alternaria*, *Aureobasidium*, *Cephalosporium* species, *Absidia corymbifera*, *Eurotium amstelodami*, *Wallemia sebi*

ANIMAL PROTEINS

Examples: Bird proteins, fish meal, rat urine, mollusk shell, wheat weevil, silkworm larvae

CHEMICAL SENSITIZERS

Examples: Isocyanates, acid anhydrides, pyrethrum, Pauli's reagent (sodium diazobenzene sulfate)

areas, wallpaper, upholstery, areas of increased moisture such as shower curtains, window moldings, window air conditioners, damp basements, and emissions from cool mist vaporizers. Many fungal species have been associated causally with HP.⁷ *Aspergillus* spp. have been associated with HP in soy sauce brewers; bird breeders; farmers; compost, sawmill, mushroom, greenhouse, tobacco, cane mill, grain, and brewery workers; and in those exposed to contaminated esparto grass used in the production of ropes, canvas, sandals, mats, baskets, and paper paste. Similarly, *Penicillium* spp. may cause HP in cork workers, cheese workers, peat moss processors, laboratory workers, farmers, onion and potato sorters, sausage makers, and tree cutters.⁸ *Alternaria*, *Cladosporium*, *Aureobasidium*, *Paecilomyces*, *Fusarium*, and many other fungal species have been associated with HP in sawmill workers, tree cutters, hardwood processors, chicory leaf handlers, and other wood and plant handlers.^{9,10} There are several case reports of musical instruments (trombone and saxophone player's lung) contaminated with fungal species that caused HP in their users.^{11,12} A case of childhood HP from *Aureobasidium* contamination of indoor hydroponic cultivation has been described, with marked improvement with removal of the offending plants.¹³ Summer-type HP, the most prevalent form of HP in Japan, is caused by seasonal mold contamination (mainly *Trichosporon asahii*, formerly *Trichosporon cutaneum* serotype II) in the home, often from moldy wood flooring.^{14,15} Domestic fungal exposure associated with decaying wood and damp walls in inner city dwellings is the most common cause of HP in Australia.¹⁶ There, multiple fungal species were identified in the homes of individuals with disease, suggesting that sensitizing microbial exposures may be complex mixtures and that disease is not always attributable to a single, well-defined exposure.

ANIMAL PROTEINS

Particulates from a variety of animal sources can cause HP when inhaled. Exposure to bird protein antigens, first described in 1960, is the most clinically important and well recognized and is referred to as "bird breeder's" or "bird fancier's lung." Avian antigens are complex high- and low-molecular-weight proteins found in the feathers, droppings, and serum of turkeys, chickens, geese, ducks, parakeets (budgerigars), parrots, pigeons, doves, love birds, canaries,

and even native birds and are highly immunogenic.¹⁷ Immunoglobulins, particularly *immunoglobulin* (Ig) A and IgG, are released from birds' feathers, creating a fine dust called "bloom." Flying birds such as pigeons and parakeets produce the largest amount of bloom and are the birds most often associated with HP.¹⁸ Pigeon fancier's lung may also be caused by IgG secreted on pigeon intestinal mucin.^{19,20} Highest exposures to respirable avian antigens are associated with cleaning out bird lofts, cages, and coops. Indirect and apparently trivial antigen exposures also have been associated with avian HP. Goose feather duvets, down comforters and pillows, feathers used for making fishing lures, and those contained in decorative wreaths have all been associated with HP.²¹ These findings suggest that avian antigens are extremely potent inducers of immunologic lung disease, and a careful search for their presence must be included in the history taking of patients with suspected HP. These antigens can also be highly resistant to degradation, and antigenic similarity across various bird species mandates a thorough removal of all bird and feather products for a patient with bird fancier's lung.^{22,23} Even with extensive cleanup following removal of birds from indoor environments, antigen exposure may persist for months to years, perhaps explaining the lack of improvement in some patients with this form of HP.²⁴

There are several other animal exposures less commonly associated with HP. Animal handlers, including laboratory and veterinary workers, can develop HP from exposure to inhaled proteins in serum and excreta from rats and gerbils. Inhalation of grain dust infested with the wheat weevil *Sitophilus granarius* can cause a form of HP known as "miller's lung." Sericulturists engaged in silk production can develop HP from exposure to larval secretions and cocoon particulates.²⁵ Production workers exposed to mollusk shell dusts during cutting and polishing to make buttons may develop HP.²⁶

CHEMICAL SENSITIZERS

HP from inhalation exposure to low-molecular-weight chemicals is probably less common than from the other causes. Isocyanates are used for large-scale production of polyurethane polymers for flexible and rigid foams, as elastomers, adhesives, and surface coatings, and in two-part paints and are becoming increasingly recognized as a cause of HP.^{27,28} Acid anhydrides used in plastics, paints, and epoxy resins have been associated with an HP-like syndrome.²⁹ Rare case reports of HP have been described from exposure to the pesticide pyrethrum; from Pauli's reagent (sodium diazobenzene sulfate) used in chromatography; from copper sulfate in Bordeaux mixture used to spray vineyards; and from the enzyme phytase used as a cattle feed additive.³⁰ Other chemical exposures reported to cause HP include formaldehyde, dimethyl phthalate, and styrene, the latter used in boat manufacturing.^{31,32}

EXPOSURE SETTINGS AND RISK FACTORS

Although the acute symptoms of HP are often attributed to intense, intermittent antigen exposure whereas more

subtle, insidious symptoms are thought to result from lower level, more prolonged exposure, the paucity of environmental exposure data provides little insight into dose-response relationships. Insight into exposure-response relationships is further complicated by the fact that the latency period between exposure to an environmental antigen and onset of HP symptoms may vary from a few weeks to years.

Environmental risk factors—including particle size and solubility; antigen type and concentration; exposure duration, frequency, and intermittency; use of respiratory protection; and variability in work practices—may influence disease prevalence, latency, and severity. FLD is most common in late winter, when stored hay is used to feed cattle, and in regions with heavy rainfall and harsh winter conditions, where feed is likely to become damp and therefore an ideal substrate for microbial proliferation. A seasonal variation in specific antibody levels has been described in patients with pigeon breeder's disease, with a peak in antibody production during late summer, when highest exposures were associated with the sporting season.³³ There is wide geographic variability in the spectrum of indoor mold contaminants, where moist or humid environments foster growth.³⁴ Thus the most common forms of HP show both seasonal and geographic variation.

EPIDEMIOLOGY

The worldwide prevalence of HP is unknown. Reported disease incidence, prevalence, and attack rates vary widely and depend on the populations studied, the nature and intensity of antigen exposure, the case definition chosen, and variable host factors. In Europe, HP constitutes 4% to 13% of all interstitial lung diseases.³⁵ Epidemiologic studies of agricultural workers and bird fanciers suggest that HP is quite common in some high-risk occupational settings. Questionnaire surveys of farming communities found prevalence rates ranging from 2.3% to 20%. Country-wide reporting systems that collect data on clinically confirmed HP in Finnish farmers showed a mean annual incidence rate of 44 per 100,000; a Swedish study showed a rate of 23 per 100,000.³⁶ The reported prevalence of pigeon breeder's disease varies between 1 and 100 per 1000 breeders.³⁷ Rates of avian HP in the United Kingdom averaged 0.9 cases per 100,000 person-years between the years 1991 and 2003.³⁸ Fewer data exist on the prevalence of HP in workers exposed to chemical antigens. Isocyanate-induced HP was identified in 8 (4.8%) of 167 workers employed in a wood chipboard manufacturing plant.³⁹ Of the cases in which a causative agent was identified, 17% were due to various chemical agents, with isocyanates the most frequently reported.⁴⁰

HP can present in infants and children, although the incidence and prevalence are unknown. Avian proteins are the most common antigen associated with HP in the pediatric population. In one study of 86 pediatric HP cases, 70 were caused by birds.⁴¹ HP should be considered in the differential diagnosis of children with recurrent febrile respiratory illnesses and in those with unexplained interstitial lung disease.⁴² Parents should be questioned carefully regarding potential antigen exposures in the home,

school, and avocational settings such as indoor recreation centers.

CLINICAL PRESENTATION

HP is a syndrome marked by lung inflammation in response to an inhaled antigen in a sensitized host. However, the nature of the immune response and the associated clinical manifestations vary because of differences in the intensity of antigen exposure, the chronicity of antigen exposure, and individual host factors. Historically, three distinct clinical phenotypes have been recognized: acute, subacute, and chronic HP. *Acute* HP refers to the development of respiratory insufficiency or failure within hours after intense exposure to an antigen to which the patient has been previously sensitized. In contrast, patients with *subacute* HP have a more insidious presentation, in which symptoms develop over weeks to months, and for which the antigen concentration is likely lower than acute HP. Although pulmonary symptoms may be quite limiting, respiratory failure is not a typical feature of subacute HP. Historically, *chronic* HP described disease activity lasting beyond several months. In its current usage, chronic HP refers to findings of pulmonary fibrosis. For clarity and precision, we refer to this clinical phenotype as *chronic fibrotic* HP. It is thought to be due to prolonged exposure to low levels of antigen, and patients with this phenotype present with an even more insidious onset of symptoms. Signs of active inflammation on imaging or histologic findings are variable in chronic fibrotic HP.

There are limitations to these descriptors of clinical phenotypes. Subacute disease may persist and evolve to a chronic process, with or without fibrosis. In addition, there can be overlap. On imaging and histopathologic examination, subacute and chronic fibrotic changes frequently coexist. The recurrence of high-level exposures leading to acute HP events may be superimposed on a background of subacute or chronic fibrotic HP. While acknowledging these limitations, we discuss the features of HP based on these phenotypes because they work reasonably well to capture distinct immunopathologic processes and their clinical correlates.

IMMUNOPATHOGENESIS

The pathogenesis of HP is complex and for all three clinical phenotypes involves (1) repeated antigen exposure, (2) immunologic sensitization of the host to the antigen, and (3) immune-mediated damage to the lung. Even with these shared features, each phenotype has distinguishing features. These are addressed later, acknowledging that the immunopathologic features have been best defined for subacute disease.

The *bronchoalveolar lavage* (BAL) cellular profile of acute HP demonstrates a robust acute alveolitis in which an influx of neutrophils, peaking 48 hours after exposure, is followed by an increase in CD4⁺ lymphocytes.⁴³ Although early neutrophil accumulation is associated with the onset of systemic symptoms and pulmonary abnormalities, there are limited data on the nature and extent of neutrophil activity in the pathophysiologic characteristics of acute HP. The subsequent increase in lymphocytes is observed

between 48 and 72 hours and is due to both cellular redistribution from peripheral blood to lung and lymphocyte proliferation locally. The accumulation and expansion of CD8⁺ lymphocytes can lag that of CD4⁺ lymphocytes, and the ratio of CD4⁺/CD8⁺ cells, although often decreased in subacute HP, is less predictable in acute disease.^{44,45} Alveolar macrophages demonstrate an activated phenotype and produce reactive oxygen species that are thought to contribute to alveolar damage.⁴⁶ Cytokines and chemokines released from lymphocytes and antigen-presenting cells contribute to the proinflammatory milieu and perpetuate the inflammatory response. This response continues until antigen is cleared or until intrinsic mechanisms down-regulate the immune response. Although a pathogenic role for immune complex deposition (a type III hypersensitivity reaction) has been considered for acute HP, this remains to be established.²³

In subacute HP, robust engagement of adaptive immune responses is reflected in a pronounced BAL lymphocytosis, composed of CD4⁺ and CD8⁺ cells. Cell-mediated type IV hypersensitivity inflammation, the delayed type of hypersensitivity involving CD4⁺ T cells stimulating CD8⁺ cells to destroy targets, is central to the pathogenesis.⁴⁷ Interstitial and peribronchiolar lymphocyte accumulation and granuloma formation are predominate findings. The ratio of CD4⁺/CD8⁺ cells is often low, although not always.⁴⁸ Whether this is due to preferential expansion or survival of CD8⁺ lymphocytes in HP is not clear.⁴⁵ Similarly, the contribution of a cytotoxic effect of CD8⁺ lymphocytes to the pathophysiologic changes of HP remains poorly defined.^{49,50} CD4⁺ lymphocytes in HP polarize to a *type 1 T helper* (Th1) phenotype. Cytokines secreted by Th1 lymphocytes and macrophages, including interferon- γ , tumor necrosis factor- α , and interleukin-18, promote granuloma formation.⁵¹

The pathogenesis of chronic fibrotic HP is incompletely understood. Low-level antigen exposure, leading to subclinical disease, may permit the development of occult fibrosis in patients who are not alerted by symptoms to alter their exposure. However, it is not known to what extent fibrosis in HP develops as a sequela of nonresolving subacute HP or if it is a categorically discrete subtype in which the immune response is less inflammatory and more profibrotic from the outset. In either case, cellular profiles provide insight into possible mechanisms of disease; in chronic HP, effector T-cell function is lost, a shift toward a profibrotic Th2 lymphocyte profile is noted, and a higher CD4⁺/CD8⁺ ratio is often observed.⁵² Polarization of CD4⁺ lymphocytes to a Th2 phenotype may be important for the fibrotic response. In an animal model of HP, mice genetically programmed for enhanced Th2 activity were more likely to develop pulmonary fibrosis.⁵ In a study of patients with HP, those with fibrotic disease had a higher percentage of lymphocytes with Th2 properties compared to patients with subacute disease. More work is needed to understand both the early inflammatory events of chronic HP and the role of lymphocyte polarization and macrophage activity in the development of fibrosis. These patients often have an insidious clinical presentation, presenting with well-established fibrosis. In such cases the early immune events that proceeded and potentially promoted fibrogenesis are unable to be ascertained in retrospect.

HOST FACTORS

Following antigen exposure, more people develop precipitating antibodies than develop symptomatic HP. Susceptibility to or protection from HP may be explained in part by genetic polymorphisms.⁵³ Polymorphisms in the major histocompatibility complex and in tumor necrosis factor- α are associated with the development of HP.⁵⁴⁻⁵⁶ Within the major histocompatibility complex, polymorphisms of human leukocyte antigen genes and of the transporters associated with antigen processing 1 (*TAP1*) gene have been associated with increased risk for HP.^{54,55,57-59} Several polymorphisms have also been associated with decreased disease risk. Overexpression of GATA3, a regulator of Th2 differentiation, attenuates disease perhaps by correcting the Th1 immune response.⁶⁰ Variants in the tissue inhibitor of metalloproteinase-3 also appears to be protective.^{61,62}

Nongenetic host factors are also important disease determinants. HP develops more frequently in nonsmokers than in smokers. Compared with former and never smokers, pigeon fanciers who smoked had lower levels of serum IgG and IgA antibodies to pigeon proteins; this suggests that factors associated with cigarette smoking depress both T-cell-dependent and T-cell-independent responses to inhaled antigens.⁶³ In an experimental HP model, nicotine exposure was associated with reductions in cellular responses, lymphocyte and total cell counts in BAL, and lung tissue inflammation.⁶⁴ Other studies have shown that smoking induces relative increases in lung macrophages and decreases in lymphocytes and dendritic cells, perhaps promoting more effective clearance of antigens from terminal airways.^{65,66}

In addition to the risk factors for developing disease, variations in immune responses due to patient characteristics are also important determinants of the clinical phenotype of HP. Although HP is more common in nonsmokers, the prognosis is poorer in those with HP who smoke. In one study, smokers with FLD had more frequent illness recurrence, had lower percent predicted vital capacity, and had poorer 10-year survival in comparison with nonsmokers with FLD.⁶⁷ Smokers are more likely to have insidious than acute symptoms, which may delay clinical recognition. In addition to smoking status, age may play a role in the phenotype of disease, where immune responses change with age. In a study of clinical features of patients with nonacute HP, those who developed fibrosis were significantly older than those who did not develop fibrosis.⁶⁸

HISTOPATHOLOGY

The histopathologic features of acute HP are poorly understood, because biopsies in this setting are generally not performed. When available, results of biopsies show lymphocytic interstitial infiltrates and a neutrophilic and lymphocytic alveolitis. Foci of eosinophilic infiltrates can also be observed. Granulomas, which take days to weeks to develop, are not apparent in new-onset acute HP.

The histopathologic findings of subacute HP have been better characterized than those of acute HP. The classic histologic triad includes (1) cellular bronchiolitis, (2) interstitial mononuclear cell infiltrates, and (3) scattered, small,

Figure 64-1 Granulomatous involvement seen in hypersensitivity pneumonitis. **A**, Several poorly formed non-necrotizing granulomas are present (arrow). **B**, Airway-centered interstitial fibrosis is seen together with giant cells (arrows). **C**, A bronchiolocentric distribution may be evident, as indicated by the presence of a terminal bronchiole or by some degree of nodularity to the infiltrates at low magnification. **D**, Multinucleate giant cells may also be seen in the interstitium and constitute a helpful feature at low magnification in drawing the eye to features meriting closer examination.

non-necrotizing granulomas (Fig. 64-1).⁶⁹ A cellular bronchiolitis in which lymphocytes and plasmacytes infiltrate respiratory bronchioles is a hallmark of subacute HP. The interstitial lymphocytic infiltrate is most prominent in peribronchiolar areas, although its distribution may be more uniform and thus similar to *nonspecific interstitial pneumonia* (NSIP); in such cases, coexisting granulomas are a helpful distinguishing feature.⁷⁰ Granulomas in HP are often distinct from those of sarcoidosis, although granuloma characteristics alone should not be used to distinguish these two diseases. Except in hot tub lung, in which granulomas may be well formed, HP granulomas tend to be smaller, less numerous, and more loosely organized than sarcoid granulomas.⁷¹ Because they seldom hyalinize, HP granulomas often resolve after antigen clearance and avoidance.⁷² Granulomas in HP form in bronchiolar walls and alveolar tissue. Whereas constrictive bronchiolitis is an uncommon finding, focal areas of organizing pneumonia have been observed in subacute HP.⁷²

The chronic fibrotic form of HP is characterized by airway-centered interstitial fibrosis and giant cells, often with minimal or absent granulomatous inflammation (see Fig. 64-1B).⁷² Bridging fibrosis may be observed between peribronchiolar and perilobular areas. Organizing pneumonia, cellular NSIP, fibrotic NSIP, and usual interstitial pneumonia with honeycombing and fibroblast foci are well-described patterns variably observed in chronic fibrotic HP.⁷²⁻⁷⁴ Coexisting histopathologic features that support a diagnosis of HP over other clinical entities include the

presence of granulomas, giant cells, bridging fibrosis, or chronic bronchiolitis. When the histopathologic features remain equivocal, additional clinical data must be considered in confirming the diagnosis.^{70,73-75}

Acute exacerbations have been reported in chronic fibrotic HP. Histopathologic findings from lung biopsies obtained during such exacerbations reveal diffuse alveolar damage, akin to findings in acute exacerbations of idiopathic pulmonary fibrosis.⁷⁶ It is not clear how often such exacerbation events in HP are due to antigen reexposure or to a complication of the underlying fibrotic process.

CLINICAL FEATURES

SIGNS AND SYMPTOMS

Acute HP typically begins hours after antigen exposure, with the abrupt onset of flulike respiratory and constitutional symptoms, including cough, dyspnea, chest tightness, fevers, chills, malaise, and myalgias. Symptoms may be accompanied by physical findings of fever, tachypnea, tachycardia, and inspiratory crackles on lung examination. A peripheral blood leukocytosis with neutrophilia and lymphopenia may be present. Eosinophilia is unusual. If antigen exposure ceases, symptoms of acute HP typically begin to resolve within days. Subacute HP has a more insidious presentation, in which progressive dyspnea on exertion and decreased activity tolerance are common. Cough is variably

Figure 64-2 Acute hypersensitivity pneumonitis. **A**, Chest radiograph of a patient with HP shows diffuse micronodules. **B**, High-resolution (1.5-mm thin section) CT (HRCT) image through the lung of the same patient shows profuse centrilobular micronodules. **C**, HRCT scan of a different patient with bird breeder's lung shows diffuse ground-glass attenuation with reticular opacities and centrilobular micronodules.

present. Although there may be low-grade fevers and weight loss, systemic symptoms are not as prominent or as prevalent in subacute HP as in acute HP.⁷⁷ On lung examination, inspiratory crackles are common, and squeaks are variably present. Alternatively, the lung examination findings may be entirely normal.⁷⁷ Patients with chronic fibrotic HP often present with slowly progressive dyspnea on exertion and a nonproductive cough; they may uncommonly report wheezing, sputum production or chest tightness.^{77,78} Weight loss, if present, is often mild, and patients may report fatigue and decreased stamina. Similar to subacute HP, fever and other systemic symptoms are not as prominent in chronic fibrotic HP as in acute HP. Examination may reveal hypoxemia, at rest or with exertion, and basilar crackles are common. Cyanosis and right-sided heart failure can be seen in severe fibrotic disease. Digital clubbing, when present, is associated with a poorer prognosis.⁷⁹

LUNG FUNCTION

Complete *pulmonary function tests* (PFTs), including lung volumes, spirometry, and diffusing capacity for carbon monoxide, should be obtained in all patients with suspected HP who are clinically stable enough for testing. Although PFT results may be normal, most often abnormalities are detected, although none are specific for HP. A reduction in the diffusion capacity is common in all HP phenotypes and may be the most sensitive pulmonary function alteration. Lung function abnormalities in HP are classically restrictive.^{76,80} Alternatively, obstruction or mixed deficits may be observed. The response to bronchodilators is variable, and HP should be considered in the differential diagnosis of nonsmokers presenting with either fixed or reversible obstruction. Obstruction in HP may be more common in those with fibrosis, where periairway fibrosis may contribute to airflow impairment.⁸⁰ Nonspecific bronchial hyper-reactivity on methacholine challenge can be observed.⁸¹ An exercise-induced decrease in arterial oxygen saturation is an early sign of functional impairment in patients with mild disease. In patients with significant airway or parenchymal involvement, gas exchange abnormalities can be significant

with exercise or may be evident at rest. After an initial assessment, serial PFTs should be followed to assess response to therapy and to guide treatment decisions until recovery or stability of lung function is achieved. In acute HP, lung function typically normalizes after recovery from the acute event. In subacute HP, lung function may normalize if permanent damage has not ensued. In chronic fibrotic HP, however, lung function may be permanently and severely impaired.

IMAGING

In acute HP, chest imaging typically reveals diffuse ground-glass opacities, although a fine micronodular pattern may also be observed (Fig. 64-2).^{82,83} Ground-glass opacities reflect underlying alveolitis; although they can be seen in any stage of HP, ground-glass opacities are the predominant finding in acute HP.⁸⁴ Paralleling the clinical response, radiographic abnormalities in acute HP resolve over days to weeks if further exposure is avoided (eFig. 64-1).

In subacute HP, the imaging manifestations include ground-glass opacities, centrilobular nodules (eFig. 64-2A and B), and mosaic attenuation.^{85,86} These findings are best appreciated on *computed tomography* (CT) imaging (see eFig. 64-2C and D).^{87,88} Occasionally the centrilobular nodules may be small (≤ 3 mm) and circumscribed and may be referred to as “micronodules” (eFig. 64-3), although the diagnostic and prognostic significance of this designation is unclear. Similar to acute HP, ground-glass opacities reflect an underlying alveolitis. Accompanying cellular bronchiolitis manifests as centrilobular nodules (see eFigs. 64-2B, C and 64-3C-E; Video 64-1A) and “air trapping” (see Video 64-1B). Mosaicism due to air trapping is common in HP, in which hyperlucent areas are the result of hypoxic vasoconstriction and decreased arterial blood flow in hypoventilated regions^{78,87} (Fig. 64-3). Air trapping is best assessed by comparing inspiratory (see Video 64-1A) and expiratory CT images (see Video 64-1B), where expiratory views accentuate hyperlucent areas.⁸⁹ Lung cysts, similar to those described in lymphoid interstitial pneumonia, have been reported in HP (see eFig. 69-8).⁹⁰ Hilar or mediastinal

Figure 64-3 Hypersensitivity pneumonitis. Bilateral, diffuse ground-glass opacities with mosaic perfusion reflect alveolitis and bronchiolitis, respectively.

Figure 64-4 Chronic fibrotic hypersensitivity pneumonitis. Areas of ground-glass opacity admixed with a few small areas of fairly normal-appearing lung are associated with extensive reticulation, traction bronchiectasis, and architectural distortion.

lymphadenopathy rarely is seen at chest radiography. In contrast, mild mediastinal lymphadenopathy, typically involving only a few nodes, is variably observed on CT imaging in any subtype of HP.

In chronic fibrotic HP, although radiographic findings of subacute HP are often also present, fibrotic changes predominate. The chest radiograph often reveals volume loss, architectural distortion, and fibrotic lines (eFig. 64-4A). CT findings include volume loss, traction bronchiectasis, fibrotic reticular or linear opacities, and honeycombing (Fig. 64-4; see eFig. 64-4B-D). Usual interstitial pneumonia and fibrotic NSIP are well-recognized radiographic patterns of chronic fibrotic HP, and CT imaging alone is often unreliable in differentiating chronic fibrotic HP from other fibrotic interstitial lung diseases, with an accurate diagnosis in only 50% of patients in one series.⁹¹ The degree of fibrosis on CT is associated with a poorer prognosis in patients with HP (see Fig. 64-4).^{92,93} Notably, in chronic fibrotic FLD, emphy-

sema not related to smoking is a more common radiographic finding than fibrosis.^{94,95}

BRONCHOALVEOLAR LAVAGE AND OTHER LABORATORY TESTING

Typically, acute and subacute HP are characterized by a marked increase in BAL white blood cell count and a BAL lymphocytosis (30% to 70%), often with a CD8⁺ lymphocyte predominance; this is less true in fibrotic HP. The absolute number of macrophages is similar to that in controls, although their percentage is reduced because of the high percentage of lymphocytes. These typical findings notwithstanding, the BAL cellular profile may vary considerably, depending on the stage of illness and on the time since the last antigen exposure. There appears to be little correlation between BAL findings and other clinical abnormalities, including radiographic changes, pulmonary function, and the presence of precipitating antibodies.

Mild serum elevations in erythrocyte sedimentation rate, C-reactive protein level, and immunoglobulins of IgG, IgM, or IgA isotypes are variable findings. Rheumatoid factor can be elevated.⁷¹ However, antinuclear antibodies and other autoantibodies rarely are detected and, if found, suggest an underlying connective tissue disease.

DIAGNOSING HYPERSENSITIVITY PNEUMONITIS

A number of diagnostic criteria for HP have been proposed, but there remains no gold standard test or approach.⁷⁶ One widely cited set of criteria includes these findings: (1) symptoms compatible with HP, (2) evidence of exposure to an appropriate antigen by either the history or antibody testing results, (3) symptom periodicity that correlates with recurrent antigen exposure, (4) imaging findings compatible with HP, (5) a lymphocytosis on BAL, and (6) histopathologic features compatible with HP. A diagnosis of HP is made by the presence of at least four of these, in addition to findings of crackles on lung examination, a reduction in the diffusion capacity, and/or hypoxemia, and when other diseases have been appropriately ruled out.⁹⁶ Although widely used, these criteria have not been validated. A subsequent clinical prediction model found the following features to be highly predictive of active HP: (1) exposure to a potential HP antigen, (2) positive antibody testing to the offending antigen, (3) episodic symptoms, (4) symptom onset within hours of antigen exposure, (5) crackles on lung examination, and (6) weight loss.⁹⁷ This model was developed from a cohort of patients with either HP or non-HP lung disease and was validated in a follow-up cohort of patients with HP. Patients with chronic fibrotic HP were not included, and applicability of this prediction model to patients with this phenotype is unknown. More recently, a published algorithm emphasized the importance of CT changes typical of HP, lymphocytosis on BAL, and positive antibodies in the setting of antigen exposure in order to diagnose HP without a surgical lung biopsy.⁴ The various proposed sets of criteria, models, and algorithms have in common an emphasis on the constellation of clinical,

radiographic, and biopsy findings in the context of the exposure history to arrive at a diagnosis of HP (Table 64-2). In addition, other diseases that have clinical features similar to HP need to be considered and excluded (Table 64-3).

EXPOSURE HISTORY

A thorough and detailed history remains the cornerstone of HP diagnosis (Table 64-4). A temporal relationship between symptoms and particular activities can be identified in some cases of acute and subacute HP and is particularly suggestive of the diagnosis, although such a

relationship is often not clinically apparent. Recurrent episodes of otherwise unexplained respiratory and systemic symptoms should prompt consideration of HP and a careful search for relevant exposures. In some cases, exposure may be frequent or sustained enough that discrete fluctuations in clinical status associated with exposure will not be evident.

Antigen exposures capable of causing HP can take place in almost any indoor environment under appropriate circumstances, and a simple job title cannot be used to exclude potential risk. The work history should include a chronology of current and previous occupations, with a description

Table 64-2 Typical Clinical Features of Acute, Subacute, and Chronic Hypersensitivity Pneumonitis

Diagnostic Approach	Acute HP	Subacute HP	Chronic Fibrotic HP
Time course of presentation	<ul style="list-style-type: none"> Acute onset of symptoms hours to days after exposure Exposure to high antigen concentration often recognized 	<ul style="list-style-type: none"> Subtle onset of symptoms over weeks to months Periodicity of symptoms corresponding to intermittent exposure may be evident 	<ul style="list-style-type: none"> Insidious onset of respiratory symptoms Clinical periodicity is often lacking
Symptoms	<ul style="list-style-type: none"> Dyspnea at rest, chest tightness, cough Pronounced systemic symptoms, including diffuse aches and fevers 	<ul style="list-style-type: none"> Dyspnea on exertion, cough, chest tightness Fatigue, low-grade fevers, myalgias are common but variable 	<ul style="list-style-type: none"> Dyspnea on exertion, \pm cough Fever and aches are less pronounced; weight loss and fatigue may be common

Table 64-4 Components of an Occupational and Environmental History for Patients with Suspected Hypersensitivity Pneumonitis**OCCUPATIONAL HISTORY**

Chronology of current and previous occupations (with major attention to employment activities within the past several years)
 Description of job processes and specific work practices (including recent changes in production processes or practices)
 List of specific chemicals, dusts, and other aerosol exposures (e.g., grain dust; animal handling; food and plant processing; cooling towers, fountains, and other water sprays; metalworking fluids)
 Review of safety data sheets (SDS or MSDS) to identify known chemical sensitizers
 Review of industrial hygiene evaluations or environmental testing at the workplace
 Symptom improvement away from work or worsening with specific workplace exposures
 Presence of persistent respiratory or constitutional symptoms in exposed coworkers
 Use of respiratory protection at work

ENVIRONMENTAL AND RESIDENTIAL HISTORY

Pets and other domestic animals (especially birds)
 Hobbies and recreational activities (especially those involving chemicals, feathers or fur, plant materials, and organic dusts)
 Presence of humidifiers, dehumidifiers, evaporative coolers, clothes dryers vented indoors, and other humidity sources
 Use of hot tubs or saunas
 Leaking or flooding indoors
 Water damage to carpets or furnishings
 Visible fungal growth or reports of musty or moldy odors
 Feather pillows, comforters, or bedding
 Similar symptoms in other family members or home occupants

MSDS, Material Safety Data Sheet; SDS, Safety Data Sheet.

of specific work processes and exposures. The environmental history should explore exposure to animal proteins, particularly birds or feathers; hobbies such as gardening and lawn care, which may involve sensitizing chemical exposures like pyrethrums; recreational activities, for example, use of hot tubs, indoor swimming pools, or saunas from which microbial bioaerosols can be generated; use of humidifiers, cool mist vaporizers, and humidified air conditioners, which can be sources of microbial bioaerosols; moisture indicators such as leaking, flooding, or previous water damage to carpets and furnishings; and visible mold or mildew contamination in occupied spaces, sometimes with musty or moldy odors.

Although a suggestive exposure history is included in most published diagnostic criteria, in many cases a causal antigen is not identified. This may be the result of inadequate occupational and environmental history taking or because of exposure to a novel causative antigen. In fibrotic HP, antigen exposure may no longer be ongoing, and, even in the setting of complete exposure histories, up to 30% of cases have no causal exposure identifiable.⁹⁸

ANTIBODY TESTING

In general, precipitating and other antibody tests are neither sensitive nor specific for HP.⁹⁹ When positive, antibody tests can be helpful in confirming the diagnosis in bird breeder's lung and in other circumstances in which the putative antigen has been identified. In a study from France where an antigen panel containing common local microbial

agents was tested in patients with HP and compared to healthy control farmers, sensitivity and specificity were quite good.⁷ However, antibody testing is not recommended as a screening tool because, in exposed populations, positive test results have a poor specificity for disease.¹⁰⁰ The finding of specific IgG-precipitating antibodies indicates exposure sufficient to generate a humoral immunologic response, but it is not strongly associated with disease. In a large series of patients with bird fancier's HP, where 92% had positive serum IgG antibodies, 87% of controls who were similarly exposed to birds but did not develop HP also had positive precipitins.⁷⁷ More sensitive assays such as the enzyme-linked immunosorbent assay and electrosyneresis to detect specific IgG antibodies may lead to confusion because of decreased specificity.⁷ However, there may be false-negative results, and negative precipitins should not be used to exclude the diagnosis. False-negative results can be due to poorly standardized antigens, improper quality controls, insensitive immunologic techniques, the wrong choice of antigen, or underconcentrated sera. In addition to these test parameters, serum precipitins may disappear over time after exposure ceases or may be undetectable in patients with low-level antigen exposure.¹⁰¹ In cases of complex microbial bioaerosol exposures, disease may not be a reaction to one organism alone but a cumulative reaction to a number of airborne antigens, which may not be reflected in available laboratory antigen panels. Therefore, despite advances in detection of serum antibodies, challenges in their use and interpretation persist.¹⁰² In addition, skin tests for both immediate and delayed-type hypersensitivity reactions are not helpful in the diagnosis of HP.^{100,103,104}

BRONCHOALVEOLAR LAVAGE

BAL is a generally safe and sensitive tool to confirm the presence of alveolitis in patients with HP. In nonsmoking patients with radiographic evidence of an active inflammatory disease process, a lack of BAL lymphocytosis argues against HP. Even in predominantly fibrotic HP, the relative and absolute lymphocyte count is still often elevated, albeit less so than in acute and subacute disease.^{68,105} Although BAL lymphocytosis is a sensitive finding in HP, it is not specific. Similar to the formation of precipitating antibodies, individuals exposed to HP antigens may develop a lymphocytic alveolitis but have no symptoms or other clinical abnormalities. In addition, the lymphocytosis may persist for years after apparent removal from antigen exposure and despite improvement in other clinical parameters, limiting its utility as a tool to follow the course and progression of disease or to assess adequacy of antigen avoidance.¹⁰⁶

LUNG BIOPSY

When the risk-benefit ratio is reasonable, obtaining 8 to 10 transbronchial biopsy samples may be a prudent approach to increasing the diagnostic yield in patients undergoing bronchoscopy for initial HP evaluation. Interstitial lymphocytic inflammation and granulomas can be seen; however, appreciation of the prototypical airway-centered inflammation in subacute HP usually requires a surgical lung biopsy.¹⁰⁷ Although yields of transbronchial biopsies are unpredictable, when positive they may spare a more

invasive surgical lung biopsy. Surgical lung biopsy is indicated in patients without sufficient clinical criteria for a definitive diagnosis or to rule out other diseases that require different management.¹⁰⁸ Surgical lung biopsy is also often helpful to differentiate fibrotic HP from other fibrotic interstitial lung diseases.^{68,74,75,97} Because findings may be patchy or sparse, diagnostic yield increases if biopsies are taken from multiple lobes.¹⁰⁹ In spite of some histologic findings that are highly suggestive of HP, the potential for overlap in the appearance of HP and other interstitial lung diseases often makes pathologic changes without clinical correlation insufficient for diagnosis.^{109a} Special stains and cultures are important to distinguish HP from infectious granulomatous conditions, including fungal and mycobacterial diseases. HP typically differs from sarcoidosis in the finding of inflammatory infiltrates at interstitial sites distant from granulomas and in the morphologic characteristics and distribution of granulomas. Interstitial infiltrates in sarcoidosis, if present, are seen in the vicinity of granulomas, which are well formed and perilymphatic.

INHALATION CHALLENGE

The use of laboratory inhalation challenge in the diagnosis of HP is limited by the lack of standardized antigens and techniques. Inhalation of an aerosolized antigen suspected to be causative is most helpful when acute symptoms and clinical abnormalities are part of the disease presentation and are likely to arise within hours after exposure. Inhalation challenge also may be helpful in the evaluation of new potential HP agents, though it is not widely available or standard practice at most clinical centers. Interpretation of results is often difficult, and routine inhalation challenge is not recommended in most patients with suspected HP.

NATURAL HISTORY AND PROGNOSIS

In acute HP, symptoms of fever, chills, and cough usually disappear within days after exposure ceases. Malaise, fatigue, and dyspnea may persist for several weeks. There is usually rapid improvement in lung vital capacity and diffusing capacity for carbon monoxide in the first few weeks after an acute attack, but mild abnormalities in pulmonary function often persist for several months.¹¹⁰ In general, recovery from acute HP is expected, and avoidance of antigen exposure is associated with a favorable long-term outcome. Some patients, after recovering from acute HP, remain without pulmonary impairment in spite of recurrent antigen exposure.¹¹¹ Conversely, the disease may progress despite removal from exposure.¹¹² Although uncommon, continued symptoms and/or progressive lung disease have been reported after recurrent acute attacks or even after a single severe attack.¹¹²

The subacute and chronic fibrotic forms of HP, with insidious symptoms and more subtle, progressive clinical abnormalities, are often recognized later in the course of illness and consequently have a poorer prognosis than acute disease. HP can result in asthma, emphysema, and

interstitial fibrosis (eFig. 64-5). In a study of Finnish farmers meeting strict diagnostic criteria for FLD, the risk for asthma necessitating medication was found to increase within the first 3 years after a diagnosis of FLD, with significantly higher asthma prevalence rates in the population with FLD at 5-year follow-up compared with the reference population.¹¹³ Emphysema is also associated with FLD. In a case-control study of 88 farmers with FLD, emphysema was found in 23% (in 18% of nonsmoking and 44% of smoking FLD patients).¹¹⁴ Recurrent attacks of FLD were associated with risk for developing emphysema. In another study of farmers with FLD, 50% had residual disease, and obstruction from emphysema was the most common clinical finding.¹¹⁵ Whereas emphysema is more common in chronic FLD, interstitial fibrosis is a more common outcome in chronic bird breeder's lung. When compared to patients with FLD, patients with HP from avian antigens appear to have a higher risk for developing fibrotic lung disease and poorer associated long-term survival rates.

No functional or biochemical marker exists to predict resolution or progression of HP. The BAL lymphocytosis may persist for years after removal from exposure and despite clinical recovery. Age at diagnosis, duration of antigen exposure after onset of symptoms, and total years of exposure before diagnosis had predictive value in the likelihood of recovery from pigeon breeder's lung disease.¹¹⁶ Patients with fibrotic disease have a significantly worse prognosis overall compared to those with nonfibrotic HP.^{85,93,117} The type of fibrotic features in HP may also correlate with prognosis; usual interstitial pneumonia and fibrotic NSIP findings are associated with worse long-term survival compared to cellular NSIP and other fibrotic histopathologic patterns.¹¹⁸ Diffuse alveolar damage can complicate the course of HP. Similar to idiopathic pulmonary fibrosis, these events in HP are often labeled an "exacerbation" of disease and are associated with a poor prognosis.¹¹⁹

A 23-year population-based study undertaken to investigate the mortality of HP showed that overall age-adjusted death rates increased between 1980 and 2002.¹²⁰ The authors suggest that this may be due to the concomitant decline in smoking rates in the United States and better disease recognition from use of thoracoscopic lung biopsy for diagnosis.¹²⁰ The risk for death increases with age, with rates of 0.01 per million in the 15- to 24-year-old group, compared with 0.80 per million in the 65-year-old and older group of patients with HP.^{68,92,121} Exacerbations of chronic fibrotic HP from diffuse alveolar damage are also associated with an increased risk for death.¹²²

TREATMENT

Ongoing antigen exposure can lead to progressive disease and potentially irreversible lung damage. Thus early diagnosis and avoidance of exposure are the mainstays of treatment. Importantly, the inability to identify an offending antigen has been shown to be independently associated with shortened survival.¹²³ In some cases, antigen avoidance does not lead to disease resolution, and cases of more advanced chronic HP may progress despite exposure

cessation. Pharmacologic therapy is an important adjunct in some cases.

ANTIGEN AVOIDANCE

On-site investigation of the implicated work or home environment by an experienced industrial hygienist may be helpful in cases in which the exposure history is uncertain, particularly when disease is progressive. Inspection of a suspect residence requires skill in assessing for sources of moisture intrusion and microbial contamination, including familiarity with air-handling systems. Recommendations for removal of contaminated furnishings along with other remediation strategies have not been systematically assessed for efficacy, though such efforts are frequently implemented.³⁴ Affected patients often inquire about the need for mold sampling. However, quantitative bioaerosol sampling for indoor microbial antigens is time-consuming and expensive and requires an experienced industrial hygienist and analytical laboratory. Even when properly performed, results are often difficult to interpret. Negative results should not be used to disprove disease or exposure.

In cases of home humidifier and hot tub lung, removal of the contaminated source is usually straightforward in eliminating ongoing exposure. However, in bird fancier's disease, bird removal is not enough, and a more comprehensive effort to eliminate residual feathers and droppings is essential. Avian antigens can be found in homes without birds if wild bird excrement is deposited heavily outside the house and tracked in on shoes. Avoidance of exposure by eliminating the offending antigen from the environment may be difficult in some circumstances. In five homes monitored serially after bird removal, antigen levels measured by inhibition enzyme-linked immunosorbent assay only gradually declined despite environmental control measures, including removal of the bird and rug cleaning, with high antigen levels still detectable at 18 months in one home.²⁴

When elimination of the antigen is not feasible or the etiologic agent is not identified, exposure avoidance may be accomplished by removing the affected individual from the likely antigen-containing environment. This approach may be simple and adequate for recovery. However, the social consequences and economic disruption to the affected individual may preclude strict abstinence from exposure. When antigen exposure avoidance is likely to be inadequate, regular follow-up of pulmonary function, chest imaging, and symptoms is essential to assess response to treatment and to direct efforts to mitigate ongoing antigen exposure.

Elimination of a causative antigen from the patient's environment is the first step not only in treatment but also in prevention of hypersensitivity diseases in others who may be exposed. For example, maple bark disease and bag-assosis are now quite rare in the United States after changes in the handling of organic material, resulting in diminished opportunity for microbial growth. Removal of damaged and colonized areas, disinfection, and elimination of conditions leading to seasonal mold contamination have been effective in preventing recurrence of summer-type HP in Japan.¹²⁴ Outbreaks of HP traced to microbial contamination

of ventilation systems were controlled by extensive modification and replacement of the systems and corresponding work areas.¹²⁵

PHARMACOLOGIC THERAPY

For acute attacks of HP, systemic corticosteroids are often prescribed, although controlled clinical trials are lacking. In cases in which pulmonary function abnormalities are minor, the clinical status is stable, and spontaneous recovery is likely with removal from exposure, corticosteroids are probably unnecessary. Given the paucity of treatment studies and the known side effects of systemic corticosteroids, clinical judgment and careful medical follow-up must guide individual patient management. Corticosteroid use in acute HP has not been shown to alter long-term outcomes. However, prednisone is often given in more severe cases, typically beginning at 60 mg/day, plus supplemental oxygen for hypoxemia and other appropriate supportive measures. Prednisone usually is continued for 4 to 6 weeks until there is significant symptomatic and functional improvement. If there is objective improvement, a gradual taper to minimum sustaining doses should follow; otherwise, corticosteroids should be tapered and discontinued.

For subacute and chronic fibrotic HP, the effect of corticosteroids on the course of disease has received limited study. In a study of pigeon breeders with HP, there were no significant clinical outcome differences between patients who were treated with corticosteroids and those who were not; the mean time for improvement or normalization of pulmonary function after treatment and removal from exposure was 3.4 months.¹¹⁶ In patients with subacute HP, 3 to 6 months of daily, slowly tapering prednisone may be adequate for disease remission. However, in those with progressive or persistent inflammatory HP, sustained corticosteroid treatment may be necessary. In a patient presenting with what appears to be end-stage chronic fibrotic HP, it may be worth a short trial (2 to 3 months) of prednisone with pretreatment and posttreatment PFTs to assess for a component of treatable disease. Although empiric, inhaled corticosteroids and β -agonists may be helpful in patients with HP manifested by symptoms of chest tightness and cough and with airflow limitation on pulmonary function testing. Nonsteroidal immunosuppressives such as mycophenolate mofetil and azathioprine have been used in patients with refractory HP, but efficacy has not been assessed in clinical trials, and reports of clinical response are lacking.¹²⁶ Antimycobacterial therapy is generally not required in patients with hot tub lung. Lung transplantation may be a last resort in patients with advanced fibrotic HP.

PREVENTION

Recognition of an index case of HP is often a sentinel health event, indicating the need for further investigation and intervention in the environment where others may be at risk and where opportunities for prevention may be identified. For example, efforts to reduce the risk for metalworking fluid-related HP have included enclosure of machining

operations, improved ventilation and other engineering controls to decrease metalworking fluid aerosols, and targeted worker training.¹²⁷

Indoor microbial contamination often is related to problems with control of moisture and, to a lesser extent, temperature. Source control and dilution should be used when appropriate to reduce indoor contaminants. Source control includes preventing leaking and flooding; removing stagnant water sources; eliminating aerosol humidifiers, hot tubs, and vaporizers; and maintaining indoor relative humidity below 70%. Optimal approaches for disinfection and maintenance to prevent hot tub lung remain unknown. If humidifiers are used, frequent cleaning and water changes minimize the risk for microbial growth. Dilution of contaminants can be achieved by increasing the amount of outdoor air in a building, and high-efficiency filters can be added to the ventilation system to help improve recirculated air quality. Work practices recommended to reduce the prevalence of FLD include efficient drying of hay and cereals before storage, use of mechanical feeding systems, and better ventilation of farm buildings. Education of potentially exposed workers in the use of work practices to minimize antigen inhalation and in early symptom recognition may be helpful.¹²⁸

In a few studies the efficacy of various types of respirators has been evaluated in preventing antigen sensitization and disease progression in sensitized individuals.¹²⁹ In bird breeders with HP, serum antibody levels declined by 65% over 14 months in those wearing respirators in comparison with no decline in antibody levels in those without respirators; no data were reported on changes in symptoms or pulmonary function in the two groups.¹²⁹ In another study, use of high-efficiency respirator masks resulted in nearly normal reactivity scores, including a composite of clinical, serologic, and pulmonary function indices, upon antigen rechallenge.¹³⁰ Adherence with long-term mask use is often poor, because most respirators are uncomfortable and cumbersome and interfere with communication. Dust respirators offer substantial but, in some cases incomplete, protection against organic dusts and are not recommended as preventive measures in sensitized individuals.

Key Points

- Hypersensitivity pneumonitis (HP) is a complex syndrome caused by an immunologic reaction to a variety of inhaled antigens, and the clinical findings, disease severity, and natural history are heterogeneous.

- Individuals with mild or subacute HP often escape early detection or are misdiagnosed as suffering from viral illnesses or asthma.
- Only a small proportion of exposed individuals develops clinically significant HP; even fewer develop chronic fibrotic HP.
- Genetic and host factors such as smoking status play a role in determining an individual's risk for disease.
- A high index of suspicion for the diagnosis of HP in patients with a compatible clinical presentation should prompt a comprehensive exposure history focused on microbial, bird, and low-molecular-weight chemical antigens.
- There is no gold standard test for HP; the exposure history, clinical assessment, and radiographic and physiologic findings help establish the diagnosis.
- Although the prognosis for recovery may be excellent with early disease recognition and exposure removal, patients with chronic fibrotic or emphysematous manifestations of HP often have a poor prognosis.

eFIGURE IMAGE GALLERY

eFigure 64-1 Resolution of hypersensitivity pneumonitis following removal of offending antigen. **A**, Frontal chest radiograph in a patient with shortness of breath and bronchoscopic biopsy and chest CT evidence of hypersensitivity pneumonitis (HP). The frontal chest radiograph shows bilateral areas of faintly nodular increased attenuation and ground-glass opacity. A humidifier was the suspected etiologic agent and was removed, and the patient was treated with corticosteroid therapy. **B**, Frontal chest radiograph performed after the patient had dramatic clinical improvement, 1 month after the radiograph in **A**, shows resolution of the poorly defined areas of ground-glass opacity; the chest radiograph now appears normal. (Courtesy Michael Gotway, MD.)

eFigure 64-2 Subacute hypersensitivity pneumonitis (HP): centrilobular opacities at chest radiography and CT. **A**, Frontal chest radiograph in a patient with many birds shows numerous, very small, poorly defined nodular opacities. The pulmonary opacities are best seen in the right midlung detail image (**B**). **C** and **D**, Axial CT images through the upper (**C**) and lower (**D**) lungs show diffuse, small, poorly defined ground-glass opacity centrilobular nodules (arrowheads). (Courtesy Michael Gotway, MD.)

eFigure 64-3 Subacute hypersensitivity pneumonitis (HP): micronodules at CT. **A**, Frontal chest radiograph demonstrating diffuse interstitial disease. Interstitial changes are highlighted in the right midlung detail image (**B**). **C** and **D**, Axial CT images through the upper (**C**) and mid (**D**) lungs show patchy, bilateral ground-glass opacities associated with small, solid nodules (arrowheads). **E**, Magnified image from **D** of posterior right upper lobe shows the micronodules (arrowhead) to advantage. (Courtesy Michael Gotway, MD.)

eFigure 64-4 Chronic fibrotic hypersensitivity pneumonitis (HP): imaging findings. **A**, Frontal chest radiograph shows multifocal, bilateral, midlung predominant linear and reticular opacities consistent with fibrotic lung disease. The imaging findings are not specific, but the absence of a clear basal and subpleural distribution argues against an idiopathic interstitial pneumonia as the cause. **B–D**, Axial chest CT displayed in lung windows shows multifocal, bilateral inhomogeneous lung opacity with areas of decreased attenuation (arrowheads) representing mosaic perfusion, with a noticeable lobular configuration (arrowheads, **D**). Patchy areas of ground-glass opacity, in some areas with micronodule formation (oval, **C**), are present. Areas of somewhat normal-appearing lung parenchyma are also seen. The combination of normal lung parenchyma, areas of mosaic perfusion, and ground-glass opacity with associated features of fibrotic lung disease is typical of fibrotic chronic HP. (Courtesy Michael Gotway, MD.)

eFigure 64-5 Progression of hypersensitivity pneumonitis (HP) over time from alveolitis toward fibrotic lung disease. **A**, Axial HRCT image shows minimal bilateral inhomogeneous lung opacity, with a few areas of faintly seen lobular low attenuation (*arrowheads*), which may suggest a small airway obstructive process, but the findings are subtle. **B**, Axial HRCT image performed 2 years after **A** shows more apparent inhomogeneous lung opacity with more clearly visible areas of lobular low attenuation (*arrowheads*); faintly ground-glass opacity is developing also. **C**, Axial HRCT performed 4 years after **A** shows extensive ground-glass opacity and reticulation associated with areas of lobular low attenuation (*arrowheads*).

INTRODUCTION

The lung may be involved in all *connective tissue diseases* (CTDs). The involvement is often subclinical, but its true extent may be masked by exercise limitation due to musculoskeletal features of the CTD. Patterns of lung involvement vary considerably within each CTD. The differential diagnosis is made even wider by inclusion of the drug-induced pulmonary reactions (Table 65-1) and the opportunistic infections secondary to therapy for the lung disease (Table 65-2), which may present with features indistinguishable from diffuse lung disease.

It is not surprising that the lung is involved frequently in CTDs because these are systemic syndromes, but it is disappointing that little is known about the true incidence and prevalence of lung disease because of a dearth of well-controlled, prospective, unselected series. Imprecision of nomenclature has also confused the issue. With this background, the aims of this chapter are to highlight the ways in which the lung may be involved in the most common CTDs and to indicate, when appropriate, the most usual pattern of lung disease for each CTD, with an emphasis on approaches to diagnosis and efficient management.

Interstitial lung disease (ILD) has been evaluated in much more detail in systemic sclerosis than in other CTDs, probably because patients with systemic sclerosis tend to be managed at referral centers. Controlled treatment data in ILD are largely confined to patients with systemic sclerosis. Therefore, the clinical presentation, prognostic evaluation, and management of ILD, covered in the systemic sclerosis section, can be broadly applied to the other CTDs and are not discussed in detail elsewhere in the chapter.

SYSTEMIC SCLEROSIS (SCLERODERMA)

The preliminary criteria for classification of *systemic sclerosis* (SSc) require that one major or two or more of three minor criteria be present (Table 65-3).¹ The skin changes may affect the entire extremity or the face, neck, and trunk (thorax and abdomen). Scleroderma is traditionally classified on the basis of the extent of skin disease. Limited disease can involve the face, but the trunk and limbs proximal to the elbows and knees are spared. Diffuse disease can involve any part of the body.

EPIDEMIOLOGY AND RISK FACTORS

The incidence of SSc is approximately 2 to 20/100,000/yr, with a peak incidence in the fourth to sixth decades. The prevalence is 30 to 120/100,000, with a 3:1 to 8:1 female preponderance.² Mortality rates have been remarkably consistent over the years, varying from 0.9 to 1.5/million for men and 2.1 to 3.8/million for women in the United States. The disease is present worldwide.

Although scleroderma clusters in families with other autoimmune disease, there are few reports of first-degree relatives having SSc. The importance of genetics to SSc is illustrated by a study of Choctaw Indians residing in southeastern Oklahoma. The prevalence of SSc in full-blooded Choctaws is roughly 1:200, which is significantly higher than is found in non-full-blooded Choctaws (1:3000) and strikingly higher than the global prevalence of SSc in other Native Americans in Oklahoma (1:10,000).³

Genetic involvement in the disease has been determined by the identification of chromosomal abnormalities and by

Table 65-1 Drug Toxicity: Patterns of Lung Disease That Have Been Reported as Adverse Effects of Drugs Commonly Used to Treat Connective Tissue Diseases

Pulmonary Effect	Penicillamine	Methotrexate	Gold	Cyclophosphamide	Sulfasalazine

Table 65-2 Immunosuppressive Therapy: Common Drugs Used in the Treatment of the Major Pulmonary Complications of Connective Tissue Diseases

Drug	Dose	Duration	Comments	Monitoring
Azathioprine	2.5 mg/kg/day Maximum 200 mg/day	Continuous	<ul style="list-style-type: none"> Maximal effect may not be evident for 6–9 mo but has better adverse effect profile than cyclophosphamide. May be used long term. Starting dose 50 mg daily with monitoring full blood count in case of thiopurine methyltransferase deficiency; maintenance dose from 1 mo. 	Full blood count Liver function tests
Cyclophosphamide, oral	2 mg/kg/day	Variable	Oral cyclophosphamide may be used continuously or substituted at 3 mo for azathioprine because of more favorable adverse effect profile in DLD.	Full blood count Liver function tests Urinalysis for blood
Cyclophosphamide, IV	15 mg/kg monthly for 1–6 mo	Variable	<ul style="list-style-type: none"> IV therapy for rapid induction of remission at 2–4 mg/kg/day for 3–4 days, especially for vasculitis Pulsed IV cyclophosphamide may be given at 1- to 3-mo intervals with better adverse effect profile and lower long-term cumulative dose, particularly in nonvasculitic disease 	Full blood count Liver function tests Urinalysis for blood
Cyclosporin A	5 mg/kg/day	Continuous	<ul style="list-style-type: none"> Bioavailability variable, thus blood monitoring necessary. May be used in combination with prednisolone. 	Blood pressure Urea and creatinine Cyclosporin A level
Mycophenolate mofetil	1–3 g/day	Continuous	<ul style="list-style-type: none"> Increasingly favored as best second line therapy, usually in combination with low dose prednisolone. Usually well tolerated with gastrointestinal symptoms the major side effects. 	Full blood count Liver function tests
Methotrexate	7.5–25 mg/wk	Continuous	<ul style="list-style-type: none"> Little information to support use except as second-line therapy. Pulmonary toxicity may be limiting. 	Full blood count Liver function tests
Prednisolone	1 mg/kg/day or 20 mg alternate days	Continuous	Prednisolone used alone in high dose for cellular DLD and then titrated to control. In conjunction with immunosuppressants, the low-dose regimen is used.	Blood pressure Blood glucose Weight Bone densitometry
Methylprednisolone	500–1000 mg	3–5 days	Used for aggressive induction of remission, particularly for vasculitis or acute pneumonitis, then followed by maintenance therapy of prednisolone or prednisolone plus immunosuppressive agent.	

DLD, diffuse lung disease; IV, intravenous(ly).

studies of the major histocompatibility complex genes. Although many of the early studies were serologic, more recently, polymerase chain reaction technology has been employed. With this latter approach, an association between diffuse lung disease and *human leukocyte antigens* (HLAs)—HLA-DR3, HLA-DR52a, HLA-DRB1*11, and HLA-DPB1*1301—has been recognized.^{4,5}

CHEMICALLY INDUCED SCLERODERMA-LIKE DISORDERS

A variety of agents are known to induce SSc-like disease, often with lung involvement, including D-penicillamine, tryptophan, bleomycin, pentazocine, and (particularly in men) the industrial agents vinyl chloride, benzene, toluene,

and trichloroethylene.⁶ Silica exposure increases the odds ratio of SSc, and silicosis increases the rate even further.⁷ The toxic oil syndrome, first recognized in Madrid in 1981, results from ingestion of an adulterated cooking oil containing rapeseed oil denatured with aniline.⁸ This provokes a scleroderma-like syndrome with pulmonary involvement. The association with silicone breast implants is unproved.

PULMONARY MANIFESTATIONS

More is known about the pulmonary complications associated with SSc than with any other CTD. Pulmonary involvement has emerged as the major cause of excess morbidity and mortality in SSc.⁹ The patterns of lung disease with which SSc may present are variable and are shown in Table 65-3.

Interstitial Pulmonary Fibrosis

Pathogenesis. There are several distinct, but related, aspects of pathogenesis.

PREDISPOSITION. There is good evidence that individuals are predisposed genetically to develop SSc, and there are emerging markers that define risks for diffuse lung disease. Class II major histocompatibility complex associations increase the risk of interstitial pulmonary fibrosis in SSc. The relative risk is increased if the anti-DNA topoisomerase (Scl-70) antibody is present. Recent studies have shown that there is an association between Scl-70 and an allele of the major histocompatibility complex *DPB1* gene.

The genetic susceptibility probably results in injury and an immune response. It has been shown that there are highly restricted T-cell responses to epitopes of DNA topoisomerase 1, both in healthy individuals and in those with SSc. Thus, in individuals with Scl-70-responsive T-cell clones, the autoantibody may be responsible for driving the immune response. In the lung, there is an accumulation of “memory-type” CD45 Ro lymphocytes and secondary lymphoid follicles with true germinal centers within lung biopsy samples.¹⁰ Furthermore, the T cells present within the lung express cytokines of both the *T helper 1* (Th1) and the *T helper 2* (Th2) subsets.¹¹ Genetic susceptibility is also

relevant to noninflammatory mediators on the basis of recent genome-wide association studies.^{12,13}

INFLAMMATION AMPLIFICATION. A wide variety of cytokines identified in *bronchoalveolar lavage* (BAL) fluid clearly contribute to the cascade of inflammation in the lungs.¹⁴ The most striking of these are interleukin-8 (neutrophil chemoattractant and activator), *tumor necrosis factor- α* (TNF- α ; an early cytokine involved in many pathologic processes), macrophage inflammatory protein-1 α (important in neutrophil chemotaxis), and RANTES (*regulated on activation normal T cell expressed and secreted*; important in T-cell and eosinophil recruitment and activation). It is clear, therefore, that the downstream events of the initiation result in the release of a number of proinflammatory cytokines that are responsible for further recruitment and activation of inflammatory cells at disease sites.

FIBROGENETIC FACTORS. The hallmark of SSc in both lung and skin is the accumulation of connective tissue matrix cells and proteins.^{15,16} Many factors have been studied in this regard, and a wide variety of growth factors have been identified. Perhaps the most striking of these is connective tissue growth factor, which appears to depend on *transforming growth factor- β* (TGF- β) for up-regulation and has a potent effect on collagen production, as evidenced by collagen gel retraction studies.^{17,18} TGF- β is found in high amounts in the lungs of patients with SSc¹⁹ and, when TGF- β signaling is inhibited, minor epithelial injury leads to extensive fibrosis.²⁰ *Endothelin* (ET)1 and coagulation cascade proteins are also present in high amounts in BAL fluid.^{15,21} Fibroblasts from patients with lung disease exhibit dysregulated type I collagen biosynthesis and impaired messenger RNA down-regulation. The balance of ET receptors (A and B) is modified in the lungs of patients with scleroderma, with a consistent decrease in ETA and an increase in ETB receptors.^{16,22} ET1 may contribute to epithelial-mesenchymal transition of airway epithelial cells, resulting in fibrosis.²³

EPITHELIAL DAMAGE. Although a key pathogenic event in idiopathic ILD, epithelial damage has been relatively underemphasized in disease models of pulmonary fibrosis in CTD. Abnormally rapid clearance of an epithelial tracer (DTPA, see later) and elevated serum KL6 levels, specific markers of alveolar epithelial damage, correlate with the severity of pulmonary involvement and are predictive of pulmonary disease progression in SSc.^{24,25} The intratracheal instillation of normal saline in a mouse strain with SSc features (including skin fibrosis and other universal characteristics) leads to lung injury and fibrosis, with evidence of epithelial injury on electron micrographic studies, attenuated type II pneumocyte proliferation, and persistence of the myofibroblast population after injury.^{26,27} Chronic microaspiration, believed to happen in many patients with SSc,²⁸ is a plausible trigger of recurrent epithelial injury.

A number of parallel events result in the development of lung injury and subsequent fibrosis. It is simplistic to target any one of these as being the important factor, but there seems little doubt that the key cytokines in the cascade include TNF- α (because it appears early in disease and has been shown in animal models to be a pivotal factor in lung fibrosis)²⁹ and TGF- β receptor (which up-regulates collagen gene expression and is important in connective tissue growth factor release). Other important cytokines may

include hepatocyte growth factor and insulin-like growth factor-II.^{30,31} The balance of Th1 to Th2 cytokines is also key because, when the shift is in favor of Th2 cytokines, such as in idiopathic pulmonary fibrosis, the prognosis is worse and there is a much higher eosinophil influx into the lung, in comparison with patients with SSc, in whom the Th1/Th2 ratio is balanced and there is less eosinophil influx per unit lung involvement.¹¹

Clinical Features

The prevalence of lung disease in SSc depends on the method used for detection. Symptoms or signs of lung disease are common. Dyspnea is present in roughly 55% of patients (range, 21% to 80%).³² Cough, a less frequently reported symptom, tends to be dry and nonproductive. Hemoptysis is rare but may complicate carcinoma or bronchial telangiectasia.³³ Fine crackles are heard at the lung bases and are of a “Velcro” character. Pleural rub is almost never heard. Pleuritic chest pain is uncommon. Pneumothorax is even less common. Digital clubbing is extremely rare. Secondary pulmonary hypertension with appropriate clinical features of right ventricular strain, raised jugular venous pressure, and ankle edema may be seen during the terminal stages of the disease.

The lung is involved more commonly in patients with diffuse rather than limited cutaneous SSc, but the extent of skin involvement does not correlate with lung function changes. Patients are often without symptoms, even with moderate pulmonary function impairment, but in other cases, exertional dyspnea is present when ILD is trivial or absent, due to pulmonary vascular limitation, cardiac involvement, musculoskeletal problems, general debility, loss of fitness, or a variable combination of these factors. Rarely, scleroderma of the chest wall may cause extrathoracic restriction.

Lung disease may be the first manifestation of SSc. In this setting, a history of Raynaud phenomenon is often helpful. In addition, careful examination of the capillaries in the nail beds reveals the typical feature associated with scleroderma: abnormal loops associated with capillary “dropout” (Fig. 65-1A). The presence of autoantibodies, particularly antinuclear antibodies, is helpful in suggesting a CTD etiology (Table 65-4).

Imaging

Chest radiographic abnormalities are present in 25% to 67% of patients, and lung function is impaired in up to 90%, although a large subset of patients has only a minor reduction in gas transfer or diffusing capacity (DL_{CO}). Chest radiography typically shows a reticular pattern in the lung bases and periphery in early disease. There is obvious loss of volume with more extensive reticular shadowing in more advanced disease. In this situation, honeycombing may be present (Fig. 65-1B).

Computed tomography (CT) has revolutionized the interpretation of the pattern and extent of disease. Disease is localized to the lung periphery, appearing earliest at the bases and posteriorly (Fig. 65-1C and D, eFigs. 65-1, 65-2, and 65-3). As disease becomes more advanced, it progresses superiorly, centrally, and anteriorly. Esophageal dilation is common, which can be helpful in the diagnosis if the lung disease is the first manifestation of the systemic disease (Fig. 65-1C and D).³⁴ The pattern may be “ground-glass” (reflecting either fine intralobular fibrosis or a more cellular histopathology) or an overtly fibrotic “reticular” pattern, consisting of intersecting linear abnormalities, often associated with traction bronchiectasis.³⁵ Honeycomb change is present in up to one third of cases but is usually limited in extent.³⁶

CT extent correlates moderately well with lung function variables, particularly measures of DL_{CO} .^{36a} In the absence of overt pulmonary hypertension, individuals with SSc are less hypoxemic than those with idiopathic pulmonary fibrosis, once the extent of disease on CT has been taken into account, a difference that has been ascribed to a relative absence of new vessel formation in abnormal lung in SSc.³⁷ The extent of individual patterns (ground-glass vs. reticular) is associated with the type of inflammatory cell found in BAL. More extensive reticular (consistent with more fibrosis) disease is associated with high neutrophil numbers, and this influx appears to be associated primarily with more extensive lung disease.³⁸

Gallium scans provide no added value. Technetium-99m-labeled *diethylenetriaminepentaacetic* (DTPA) acid clearance has been used in some medical centers to identify early disease and predict prognosis.³⁹ A more rapid clearance of

Figure 65-1 Radiographic appearances in patients with systemic sclerosis. **A**, Nail bed showing abnormal capillary loops in the cuticle. **B**, Chest radiograph from a patient with systemic sclerosis. Note the widespread, predominantly peripheral pattern of reticular opacities. The heart borders and the diaphragm are obscured. **C**, CT scan taken at a level just below the carina in a patient with systemic sclerosis. Note the peripheral reticular pattern that in this case is more prominent anteriorly. In this patient with subtle disease, the dilated esophagus is a clue as to the true cause of the fibrosing lung disease. **D**, CT scan taken at the level of the diaphragm in a patient with more extensive interstitial pulmonary fibrosis in the context of systemic sclerosis. Note in particular the dilated airways, indicating that the apparent “ground-glass”/consolidation pattern is dense fibrosis. Again, the dilated esophagus indicates that this disease is likely to be part of systemic sclerosis. (A, Adapted from Iaccarino L, Ghirardello A, Bettio S, et al: The clinical features, diagnosis and classification of dermatomyositis. *J Autoimmun* 48–49:122–127, 2014, Fig. 1; B–D, Courtesy Michael Gotway, MD.)

Table 65-4 Autoantibodies in Connective Tissue Disease

CTD	Autoantibody	Target	Comments
SSc	Anticentromere	Centromere proteins (CENP A-F)	20%–40% total SSc, wide racial variation 70%–80% limited cutaneous variant with pulmonary hypertension
	Scl-70	DNA topoisomerase 1	28%–70% total SSc, wide racial variation; >30% diffuse cutaneous disease with ILD
	PM-Scl	—	Scleroderma-myositis overlap syndromes
	Antinucleolar Ku	RNA polymerase-1 DNA binding proteins	8%–20% SSc suggests poorest 10-yr survival, renal crisis Scleroderma-myositis overlap syndromes
Rheumatoid arthritis	Rheumatoid factor	IgG	Seropositive disease more frequent with pulmonary nodules
	Antinuclear antibody Histone	— Histone proteins	— 5% rheumatoid vasculitis
SLE	dsDNA	dsDNA	50%–75%, strong association with nephritis
	ANA	—	90%–95%
	Ro/La	RNA transcription factors	60%/20%
	Histone	Histone proteins	>90% drug-induced lupus, 20%–30% primary SLE
	Sm	—	10% whites and 30% African Americans and Chinese
MCTD	Lupus anticoagulant	Phospholipid	20%–30%
	U1-RNP	Small nuclear proteins	Myositis overlap syndromes (10% SSc)
DM/PM	U2-RNP	—	Myositis, SLE, SSc
	Jo-1	Histidyl tRNA synthetase	20%–30% inflammatory myopathy but 50%–100% when associated with diffuse fibrosing lung disease
	PL-7	Threonyl tRNA synthetase	<3% antisynthetase syndrome
	PL-12	Alanyl tRNA synthetase	<3% antisynthetase syndrome
	EJ	Glycyl tRNA synthetase	<2% antisynthetase syndrome
	OJ	Isoleucyl tRNA synthetase	<2% antisynthetase syndrome
	Mi-2	Nuclear proteins	<8% DM, associated with acute onset of classic DM
	Ku	Nuclear proteins	Associated with myositis-CTD overlap syndromes
Antiphospholipid syndrome	Anticardiolipin	Membrane phospholipids	Disease diagnosis depends on presence of clinical features
	Lupus anticoagulant	—	—
Relapsing polychondritis	Anticardiolipin	Cartilage Collagen	Unknown sensitivity
Sjögren syndrome	Ro (SS-A)	RNA transcription factors	40%–50% primary Sjögren syndrome (25%–30% SLE)
	La (SS-B)	—	50% Sjögren (10% SLE)

ANA, antinuclear antibody; CTD, connective tissue disease; DM/PM, dermatomyositis/polymyositis; dsDNA, double-stranded DNA; IgG, immunoglobulin G; ILD, interstitial lung disease; MCTD, mixed connective tissue disease; SSc, systemic sclerosis; SLE, systemic lupus erythematosus; tRNA, transfer RNA.

this tracer from the air spaces into the circulation is indicative of a loss of epithelial cell integrity. A persistently rapid clearance rate confers an increased risk of subsequent lung function deterioration, and a persistently normal clearance rate predicts lung function stability.

Lung Function Tests

The interstitial pulmonary fibrosis of SSc is characterized by a restrictive ventilatory defect, which results in reduced pulmonary compliance, vital capacity, and total lung capacity. Residual volume is decreased. DL_{CO} is reduced and may be the only abnormality in early disease. Blood gas analysis usually reveals a normal or reduced *arterial oxygen pressure* (PO_2), reflecting regional vasoconstriction in diseased lung, with a normal or low *arterial carbon dioxide pressure* (PCO_2). In the absence of pulmonary hypertension, hypoxemia is seldom marked until late in the disease process.

There have been a number of studies of the rate of decline of lung function in SSc.^{40,41} In one study of 38 patients with SSc, the mean loss of vital capacity was 100 mL per year (20 to 30 mL/yr being the normal rate of decline).⁴¹ A second study showed that vital capacity loss was greater in patients who had evidence of an active alveolitis on BAL.³⁰ Lower *forced vital capacity* (FVC) within 3 years of disease onset predicts decline in pulmonary function.⁴² Rates of

decline are often higher within the first few years of onset of SSc, emphasizing the importance of identifying lung disease early.

Exercise lung function testing increases ventilation-perfusion mismatching and also increases diffusion abnormalities resulting in hypoxemia and widening of the alveolar-arterial oxygen difference. Minute ventilation increases generally as a consequence of increased respiratory rate rather than tidal volume. Dead space ventilation may increase with exercise, with a rise in the dead space-to-tidal volume ratio. For a given degree of lung involvement defined by CT, abnormalities on exercise gas exchange are more severe in patients with idiopathic pulmonary fibrosis than in those with interstitial pulmonary fibrosis in association with SSc.³⁷

Bronchoalveolar Lavage

BAL may identify alveolitis in SSc before the onset of pulmonary symptoms.⁴³ A neutrophil alveolitis has been described by some authors to predict more progressive disease.^{40,44,45} However, it has been shown that an increase in neutrophils reflects an increase in the extent of disease on CT, particularly of the reticular pattern; thus, this increase is likely a marker of more extensive disease rather than an independent index of progressive disease.^{38,46,47}

BAL should not be used alone to determine whether treatment should be started. Many patients with apparently normal BAL findings may exhibit progressive disease. BAL is, therefore, not recommended routinely for the diagnosis or monitoring of SSc-related interstitial disease.

Biopsy

Surgical lung biopsy is virtually never required in the diagnosis of SSc-related interstitial disease unless clinical and CT findings are atypical for ILD in SSc and an alternative diagnosis is suspected. No useful additional information is provided by transbronchial biopsy. Pathologically, the most prevalent pattern is nonspecific interstitial pneumonia, with thickening of the alveolar walls with inflammatory cells (mononuclear cells, granulocytes, and plasma cells); connective tissue matrix cells; and proteins combined with intra-alveolar inflammation (predominantly by macrophages), type II pneumocyte proliferation, and vascular obliteration. The distribution is subpleural and basal and is maximal in posterior segments, with the macroscopic findings of the lung surface taking on a fine nodular, “cirrhotic” appearance in the early stages and honeycombing with more advanced disease.⁴⁵ This pattern differs from usual interstitial pneumonia in exhibiting a homogeneous pattern of pathology (eFig. 65-4). Much less commonly, the usual interstitial pneumonia pattern of histopathology is seen. One of the hallmarks of usual interstitial pneumonia is a heterogeneous appearance, with normal alveoli seen in the same section as areas of extensive alveolar remodeling (areas of fibroblastic proliferation and dense fibrosis).⁴⁸ Crucially, outcome does not differ materially. In idiopathic disease, the usual interstitial pneumonia pattern of injury is associated with a worse outcome compared with the nonspecific interstitial pneumonia pattern.^{48a} However, in SSc, outcome is not related to the histologic pattern in the largest series,⁴⁵ although there is evidence in a smaller series that some patients with usual interstitial pneumonia pattern have a progressive course.⁴⁹ Overall, surgical biopsy data do not provide sufficient prognostic information to justify the procedure in SSc.

Electron microscopy shows early endothelial and epithelial cell injury, even without abnormalities on light microscopy. Autopsy studies show diffuse lung disease in up to 80% of cases and pulmonary vascular disease in up to 30% (eFig. 65-4C). In some patients with a more accelerated course of disease, histopathologic examination has shown a diffuse alveolar damage pattern.⁵⁰

Serologic Investigations

Although SSc is traditionally defined on the basis of the extent of the skin disease, as outlined previously, the pattern of autoantibodies appears to be a much stronger determinant of the associated internal organ involvement.^{51,52} Antinuclear antibodies are found in 90% to 100% of patients with SSc (roughly 30% of normal individuals have antinuclear antibodies at a titer of 1:40). Three major autoantibodies include anti-centromere, seen in 57% of patients with limited cutaneous disease; anti-topoisomerase (Scl-70), seen in 40% of patients with diffuse disease; and PM-Scl, seen in a small fraction of cases in association with the polymyositis overlap syndrome. It is rare to have both Scl-70 and anti-centromere antibodies. Diffuse lung disease

is rare in the presence of anti-centromere antibodies, and a protective role for this autoantibody has been argued but not substantiated. Interstitial pulmonary fibrosis is strongly associated with the Scl-70 antibody and with diffuse scleroderma. Limited cutaneous disease associates with vascular disease and the anti-centromere antibody. Both forms of lung disease may progress to pulmonary hypertension. Other autoantibody studies have shown associations with organ involvement, including a nucleolar pattern associated with diffuse lung disease and pulmonary hypertension⁵³; the antibody against B23, a nucleolar phosphoprotein, associated with pulmonary hypertension and the presence of the anti-fibrillarin antibody; and anti-Th/To antibodies associated with pulmonary hypertension and diffuse lung disease.

Prognosis

Although crude mortality rates are 3.9%/yr for men and 2.6%/yr for women, lung disease remains the most common cause of death in patients with SSc.⁵⁴ In one series, lung disease accounted for 21% of all deaths.⁵⁵ There is also an increased risk of lung cancer in SSc. With the widespread use of *high-resolution computed tomography* (HRCT), mild or trivial ILD (see eFigs. 65-1, 65-3A) is detected in many SSc patients, leaving the clinician with difficult decisions as to whether to introduce therapy or to observe carefully without immediate intervention. This dilemma is most frequently confronted in SSc but is also increasingly encountered in other CTDs. In overtly severe ILD, the decision to treat is straightforward. However, the majority of SSc patients have milder lung involvement, and a reliable means of discriminating between stable and progressive ILD would be useful in management. On the basis of clinical series and accumulated experience, prognostic evaluation should focus on three main considerations.

The decision to treat patients with SSc is most strongly influenced by the extent of disease at presentation, as judged by lung function tests (particularly FVC and DL_{CO}), and the extent of disease on CT. A simple staging system using CT extent (above and below 20%) and FVC at presentation (above and below 70%), the *United Kingdom Raynaud's and Scleroderma Association* (UKRSA) staging system, is highly discriminatory for both progression and death (Fig. 65-2).⁵⁶ The prognostic value of the UKRSA staging system has been confirmed,⁵⁷ and the severity thresholds were virtually identical to those found to identify the likelihood of a treatment effect in the first controlled study of oral cyclophosphamide in SSc.⁵⁸

The selection of patients in need of treatment is also influenced by the duration of systemic disease. The greatest risk of ILD progression is during the first 4 years of SSc. Early declines in FVC are strongly predictive of subsequent severe ILD,⁵⁹ which most often develops in the first 4 years.⁶⁰ Put simply, in SSc and other CTDs, the early development of mild to moderate ILD is a marker of likely rapid disease progression, which should reduce the threshold for initiating therapy.

Finally, evidence of recent disease progression is an important justification for treatment. It should be acknowledged that the long-term prognostic value of observed disease progression has not been quantified in SSc or, indeed, in other CTDs. However, declines in lung function

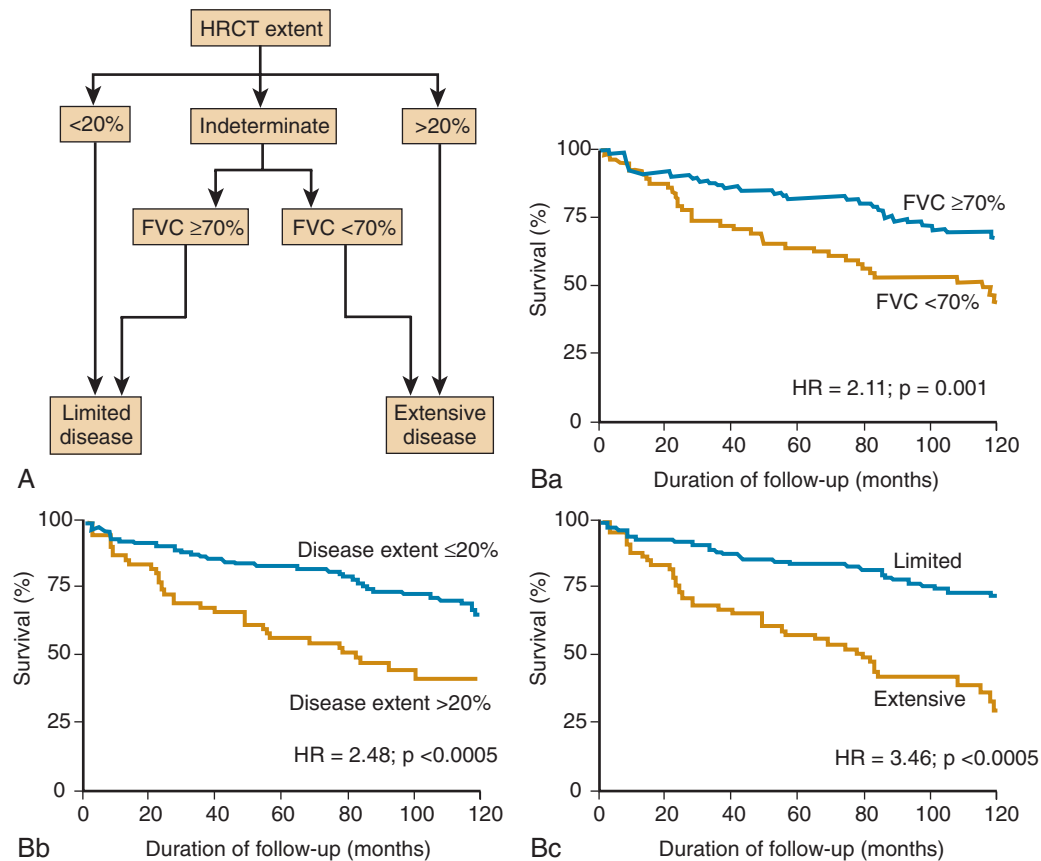

Figure 65-2 Staging algorithm for interstitial lung disease due to systemic sclerosis. **A**, Flow diagram of limited/extensive staging system with use of high-resolution CT (HRCT) scores and pulmonary function test data. Identification of overtly minimal/limited disease is based on disease extent threshold of 20% on HRCT versus severe/extensive disease that is identified by HRCT disease extent greater than 20%. In cases with an indeterminate extent of disease on HRCT, a forced vital capacity (FVC) threshold of 70% is used to separate the cases into limited or extensive disease. The HRCT scans are scored at five levels for total disease extent, extent of reticulation, proportion of ground glass, and coarseness of reticulation. **B**, Survival compared between patient subgroups with **(Ba)** FVC levels above and below a threshold value of 70%; **(Bb)** HRCT disease extent above and below a threshold value of 20%; and **(Bc)** limited disease (HRCT extent ≤ 10%, or when HRCT extent was 10% to 30%, FVC ≥ 70%) versus extensive disease (HRCT > 30%, or when HRCT extent was 10% to 30%, FVC < 70%). (Data from Goh NS, Desai SR, Veeraraghavan S, et al: Interstitial lung disease in systemic sclerosis: a simple staging system. *Am J Respir Crit Care Med* 177:1248–1254, 2008.)

variables, especially FVC, have consistently been predictive of long-term mortality in other forms of pulmonary fibrosis and these observations can reasonably be extrapolated to CTDs.

Although no overall treatment algorithm of ILD has been devised to integrate the duration of systemic disease, evidence of recent progression, and the severity of disease, consideration of all three factors provides a basis for rational treatment decisions. More recently, attention has focused on refining the selection of appropriate SSc patients with pulmonary fibrosis to participate in controlled treatment trials. In order for treatment effects to be demonstrated, it is necessary to enroll patients with progressive disease: the UKRSA staging system has recently been endorsed for this purpose by an expert group.⁶¹ Biomarker data might, in principle, be used, both in clinical prognostication and to select patients for trial involvement, but at present, despite promising preliminary data, no single biomarker is currently fit for routine use.

Treatment

A wide variety of treatments for interstitial pulmonary fibrosis in SSc have been explored.^{62,63} Most of these include

immunosuppression. A number of uncontrolled reports suggested an advantage of treatment with cyclophosphamide, together with prednisolone, to improve lung function and prognosis.^{64,65} The Scleroderma Lung Study demonstrated a small but significant benefit of oral cyclophosphamide compared with placebo for FVC, skin scores, and quality of life and dyspnea scores at 12 months.⁵⁸ The oral cyclophosphamide treatment regimen used most commonly is 2 mg/kg/day orally up to a maximum of 150 mg with moderately low dosages of prednisolone at 10 mg/day or 20 mg every other day. Close scrutiny with full blood counts, liver function tests, and urine testing for evidence of hemorrhagic cystitis is necessary.

Intravenous cyclophosphamide may have a better safety profile.⁶⁶ Studies of intravenous cyclophosphamide (750 to 1000 mg/m²) given at 2- to 4-week intervals for 6 to 12 months tended toward significance, as judged by CT and pulmonary function data.^{67,68} The similarity in the amplitude of treatment effects in the Scleroderma Lung Study⁵⁸ and a smaller placebo-controlled trial of intravenous cyclophosphamide⁶⁸ prompted the European League Against Rheumatism to state that “in view of the results from two high-quality RCTs and despite its known toxicity,

cyclophosphamide should be considered for treatment of SSc-ILD.”⁶⁹ However, it cannot be emphasized too strongly that in SSc and in other CTDs alike, careful selection of patients with severe or progressive lung disease is required, given the toxicity associated with intense immunosuppressive therapy.

In controlled trials,^{58,68} treatment effects largely consisted of the prevention or reduction in progression of lung disease, as judged by serial lung function trends, with the greatest benefit seen in patients with extensive fibrotic disease,⁵⁸ endorsing the important principle of intervention in irreversible fibrotic lung disease, with the primary aim of achieving stabilization, as opposed to regression of disease. However, in the Scleroderma Lung Study, after the cessation of active treatment, therapeutic benefits were transient.⁷⁰ Longer-term treatment approaches have not been evaluated in controlled studies. In SSc and in other CTDs, oral immunosuppressive agents that are less toxic than cyclophosphamide have been widely used, including azathioprine, methotrexate, and mycophenolate mofetil, on the basis of accumulated clinical experience and small retrospective case series.⁷¹⁻⁷³ The most convincing data were generated in a recent retrospective series of 100 CTD patients, in which treatment with mycophenolate mofetil was well tolerated and was associated, on average, with stabilization of pulmonary fibrosis over a number of years.⁷⁴

Controlled treatment data in SSc (and in other CTDs) have been confined to immunomodulatory strategies. Novel antifibrotic agents with documented treatment effects in idiopathic pulmonary fibrosis (e.g., antioxidant therapy,⁷⁵ pirfenidone⁷⁶) have not been evaluated in CTD. A well-conducted placebo-controlled trial of bosentan in SSc pulmonary fibrosis was definitively negative.⁷⁷ A study of interferon- α showed a greater deterioration in lung function at 1 year than with placebo.⁷⁸ With bone marrow transplantation in severe progressive SSc, significant improvements in lung function variables are seen in some cases.^{79,80} The most promising pilot data apply to the use of rituximab in SSc-ILD^{81,82} and, more convincingly, in polymyositis-dermatomyositis,⁸³ especially when given as rescue therapy in CTD patients with severe progressive disease despite high-dose corticosteroid and immunosuppressive therapy.^{84,84a} However, the use of rituximab in lung disease in SSc and other CTDs is currently unclear.

The question of *Pneumocystis* prophylaxis is not resolved. Some medical centers use cotrimoxazole three times a week if immunosuppressive agents are being given.

It has been observed that steroid therapy is associated with scleroderma renal crisis, both with moderate to high-dose therapy (≥ 15 mg/day prednisone or equivalent)⁸⁵ and, more recently, with prednisolone doses of less than 10 mg daily.⁸⁶ However, confounding by severity cannot be excluded, as patients with more aggressive systemic disease are more likely to receive corticosteroids, although occasional cases of renal crisis are undoubtedly linked to high-dose corticosteroid therapy.⁸⁷ Thus, low-dose steroid therapy remains justified as an invaluable adjunct to the treatment of lung disease, although renal function should be monitored.

End-stage lung disease has been treated with single-lung transplantation provided there is no evidence of disease activity in other organs and no major esophageal dysfunc-

tion. With careful selection of patients, outcome with transplantation may differ little from that in individuals with idiopathic diffuse lung disease, although it should be understood that perceived contraindications to lung transplantation due to systemic disease activity vary widely between transplant units. In terminal disease, consideration must be given to oxygen therapy, treatment of supervening heart failure, and infection and advanced care planning, with palliative care specialists often having an invaluable input.

PULMONARY VASCULAR DISEASE IN SYSTEMIC SCLEROSIS

Unlike the other CTDs, vascular involvement in SSc is caused by concentric fibrosis of small arterioles replacing the normal intima and media, but the plexiform lesions and fibrinoid necrosis of primary pulmonary hypertension are not seen. Isolated vascular disease arises mainly in the limited form of SSc. Associated features are those of the CREST syndrome (*calcinosis*, *Raynaud phenomenon*, *esophageal dysmotility*, *sclerodactyly*, and *telangiectasias*) with prominent telangiectasia, esophageal disease, abnormal nail fold capillaries (dilated capillaries and dropout of capillary loops), and a positive anti-centromere antibody. Chest radiography, CT scanning, and BAL are all normal. Lung function studies show an isolated or disproportionate fall in DL_{CO} , quantified by a decline in DL_{CO} adjusted for the alveolar volume (DL_{CO}/VA or K_{CO}) or a rise in the FVC/ DL_{CO} ratio. Although routine annual echocardiography has been advocated in all SSc patients, recent data suggest that the above-gas transfer variables can reasonably be used to select patients for echocardiography.⁸⁸ When damage to the pulmonary vascular bed is extensive (gas transfer $< 50\%$ of predicted), the risk of pulmonary hypertension increases.⁸⁹ Mortality rates increase with increasing pulmonary hypertension^{90,91} (see also Chapter 58).

Doppler echocardiography has been shown to correlate with measurements of pulmonary artery pressures made at right heart catheterization. Qualitative features found on echocardiography may also suggest pulmonary hypertension even in the absence of a tricuspid regurgitant jet that precludes measurement of the gradient across the tricuspid valve and, thus, an estimate of pulmonary artery pressure. These qualitative features include right ventricular dilation and right ventricular hypertrophy. Overall, echocardiography is moderately sensitive for the diagnosis of *pulmonary arterial hypertension* (PAH; 47% to 88%).^{92,93} However, echocardiography is less accurate at borderline and mild levels of pulmonary hypertension. Stress (exercise) echocardiography may be able to identify preclinical PAH.^{94,95} NT-proBNP, released from cardiac ventricles in response to stretch, is elevated in SSc and inversely related to gas transfer. Elevated NT-proBNP levels may predict the development of pulmonary hypertension in SSc.^{96,97} Worse functional class and impaired DL_{CO} predict worse outcomes in scleroderma-associated PAH.^{97a}

Although there are a number of emerging therapeutic options, optimal treatment of pulmonary vascular disease (see Chapter 58) in SSc has not yet been defined. Calcium channel antagonists have been used historically, but the dosage required to reduce pulmonary vascular limitation often causes unacceptable drops in left-sided pressures and

peripheral edema. Prostacyclin analogues cause potent pulmonary and systemic vasodilation and inhibit platelet aggregation. Intravenous and subcutaneous prostacyclin analogues have been shown to lead to improved pulmonary vascular resistance, pulmonary pressure, and 6-minute walk distances in the acute and longer term.⁹⁸⁻¹⁰⁰ Exact dosage regimens need to be validated, however. Inhaled iloprost may also improve exercise capacity and cardiopulmonary hemodynamics.¹⁰¹ Oral ET1 receptor antagonists have been shown to improve exercise capacity and hemodynamics in patients with PAH and CTD (including SSc).¹⁰²⁻¹⁰⁴ Sildenafil, a phosphodiesterase-5 inhibitor, leads to an improvement in exercise capacity and hemodynamics in patients with PAH (including patients with SSc).^{105,106} The correct balance of these therapies, including combination therapy, is yet to be determined in controlled studies. It should also be stressed that targeted therapy for PAH should never be introduced without the prior performance of a right heart catheter study because rapidly fatal pulmonary edema may result from occult left ventricular dysfunction due to involvement by SSc or unrelated cardiac disease. Emerging therapies, such as the platelet-derived growth factor antagonist imatinib, show promise in animal studies.¹⁰⁷

OTHER PULMONARY COMPLICATIONS

Classical aspiration pneumonia is uncommon, particularly considering the prevalence of esophageal dysfunction in SSc. It is not yet clear whether microaspiration from reflux may in some cases serve as an important cofactor leading to progression of lung disease and, therefore, active treatment of symptomatic reflux is advisable. Pleural disease is uncommon. Rarely, the extent of skin tightness over the chest wall produces an extrinsic restriction of ventilation. Occasionally, the first manifestation of pulmonary parenchymal disease is organizing pneumonia. This responds well to corticosteroid therapy, as does organizing pneumonia in other contexts.

RHEUMATOID ARTHRITIS

The American Rheumatism Association revised criteria for the classification of *rheumatoid arthritis* (RA) require that at least four of the criteria listed in Table 65-5 be satisfied for a minimum of 6 weeks.¹⁰⁸

EPIDEMIOLOGY AND RISK FACTORS

The reported incidence of RA ranges from 0.2 to 3/1000 person-years (<0.5/1000 person-years in most surveys), with a rising incidence with increasing age into the seventh decade. In adult whites, the prevalence of RA ranges from 0.5% to 2%, with a male-to-female ratio between 1:2 and 1:4. Depending on disease severity (as judged by disability scales and the need for long-term corticosteroid therapy), the age-matched mortality rate of RA is up to twofold higher than in the general population, with this increased mortality being attributed to cardiorespiratory complications.^{109,110} The prevalence of RA is similar throughout the world. Evidence in support of a genetic predisposition

Table 65-5 Rheumatoid Arthritis

CRITERIA FOR DIAGNOSIS*

Morning stiffness (lasting at least 1 hr)
Arthritis (soft tissue swelling or fluid) of 3 or more joints (PIP, MCP, wrist, elbow, knee, ankle, MTP joints)
Arthritis of hand joints (swelling of at least 1 wrist, MCP, or PIP joint)
Symmetrical arthritis (i.e., simultaneous arthritis of the same joints on both sides of the body)
Rheumatoid nodules
Serum rheumatoid factor positivity (at a level such that < 5% of normal controls are positive)
Radiographic hand or wrist changes typical of rheumatoid arthritis

LUNG MANIFESTATIONS

Interstitial pulmonary fibrosis
Organizing pneumonia
Obliterative bronchiolitis
Follicular bronchiolitis
Bronchiectasis
Vasculitis
Nodules
Pleural disease
Lymphocytic interstitial pneumonia
Drug induced

*At least 4 criteria for a minimum of 6 weeks.

MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal.

includes familial and twin clustering and associations between RA and HLA-DRB1 alleles.¹¹¹ Hormonal factors may play a role, judging from the female preponderance of RA and a reduced incidence during pregnancy. Infectious agents and socioeconomic factors have not been shown to be etiologically important.

PULMONARY MANIFESTATIONS

Pleuropulmonary manifestations are multiple and are listed in Table 65-5 and shown in Fig. 65-3.

Interstitial Pulmonary Fibrosis

The interstitial pulmonary fibrosis of RA has a male predominance (male-to-female ratio, 3:1).¹¹² High titers of rheumatoid factor¹¹³ and the presence of rheumatoid nodules^{114,115} are associated with an increased prevalence of pulmonary fibrosis in RA. Smoking is a risk factor for the development of overt pulmonary fibrosis in RA^{113,116} and has also been associated with subclinical disease.^{117,118} In the presence of HLA-DR susceptibility genes, smoking is strongly associated with development of anti-citrulline-positive RA.^{116,116a-c} It has been suggested that the seropositive RA actually starts in the lungs.¹¹⁹

In early disease, a lymphocytic interstitial infiltrate is often the predominant abnormality,¹²⁰ and prominent peribronchiolar follicles, containing aggregates of lymphocytes with germinal centers, are often seen.¹²¹ In long-standing disease, fibrosis predominates, often resulting in cystic changes or honeycombing. It is difficult to estimate the exact prevalence of subcategories of interstitial pulmonary fibrosis because, in historical series, histologic descriptions of "interstitial fibrosis" have not been detailed. Both non-specific interstitial pneumonia and usual interstitial pneumonia are present in significant proportions of patients

Figure 65-3 Rheumatoid arthritis–associated pulmonary abnormalities shown on axial chest CT. **A**, Usual interstitial pneumonia pattern (UIP). Axial prone high-resolution CT (HRCT) image shows basal, subpleural coarse reticulation, architectural distortion, and honeycombing identical to the UIP pattern in patients with idiopathic pulmonary fibrosis. **B**, Organizing pneumonia. Axial HRCT image shows bilateral peripheral consolidation (arrows). **C**, Bronchiolitis obliterans. Axial supine HRCT image shows extensive, multifocal, bilateral areas of low attenuation (arrowheads) reflecting air trapping due to small airway obstruction. **D** and **E**, Axial supine HRCT images show centrilobular ground-glass opacity nodules (arrowheads) in the right upper lobe, some of which show early cavitation (arrow), shown on biopsy to represent follicular bronchiolitis. **F** and **G**, Axial supine HRCT images show bronchiectasis in the left upper lobe, progressing over the 4-year interval between the two studies. **H–J**, Axial supine HRCT images show progressive enlargement of a rheumatoid nodule (arrows) over 1 year (**H** and **I**), with cavitation developing 3 years later (**J**). (Courtesy Michael Gotway, MD.)

with interstitial fibrosis^{122,123} (eFig. 65-5A). Usual interstitial pneumonia is associated with a better outcome in CTD than in an idiopathic setting.^{48,124,125} However, in RA, usual interstitial pneumonia is associated with a worse outcome than nonspecific interstitial pneumonia.^{126,127} Furthermore, usual interstitial pneumonia has a worse outcome in RA than in other CTDs.¹²⁸

However, even taking this fact into account, the outcome in RA patients with usual interstitial pneumonitis in the above series was somewhat better than the outcome in idiopathic pulmonary fibrosis, in keeping with trends observed in the histologic series of Park.¹²⁵ However, it is also clear that a subset of RA patients with usual interstitial pneumonia have a progressive course similar to that in idiopathic

pulmonary fibrosis, especially when HRCT appearances are similar to those in classical idiopathic pulmonary fibrosis (see Figs. 65-3A and 18-23), with predominantly basal subpleural honeycomb change and little or no ground-glass attenuation.¹²⁹

In general, surgical lung biopsies are not performed for prognostic indications in CTD. In pulmonary fibrosis in RA, it is not clear that knowledge of the histologic pattern adds usefully to HRCT assessment in prognostic evaluation, although surgical biopsies are performed in some centers. Minor pulmonary fibrosis is common in RA; in one open-lung biopsy series performed in the previous century in volunteers with RA (some without clinical evidence of ILD), pulmonary fibrosis was seen in 60% of patients.¹³⁰

Reductions in DL_{CO} are found in 40% of unselected RA patients.¹³¹ However, radiologically overt pulmonary fibrosis is found in only 1% to 5% of RA patients (based on three large chest radiographic series).^{114,117,132} In the largest prospective series reported to date, 150 consecutive patients were screened for pulmonary disease.¹³³ Of these, 19% had CT evidence of interstitial fibrosis, which was often subtle; 43% of those with interstitial abnormalities also had emphysematous bullae. Chest radiography identified abnormalities in only 14% of the whole cohort, but physiologic abnormalities were seen in 82% (gas transfer) and 14% (restrictive pattern of ventilatory defect).¹³³ Disease severity as judged by CT generally reflects functional impairment.¹³⁴⁻¹³⁶

The most frequent symptom is exertional dyspnea, although this may be masked by a general loss of mobility due to systemic disease. The clinical picture is usually identical to that of idiopathic pulmonary fibrosis, with bilateral, predominantly basal crackles and tachypnea, cyanosis, and right heart failure in advanced disease. Finger clubbing, which is occasionally striking, is more prevalent than in other CTDs. Severe progressive disease requiring hospitalization may be associated with cor pulmonale and respiratory failure and has a poor prognosis, with a 5-year survival rate of less than 50%.⁵³ A subgroup of patients has more indolent disease that progresses little during prolonged follow-up. A strong predictor of clinical decline is a gas transfer less than 55% of predicted at presentation.¹³⁷

Organizing Pneumonia

Organizing pneumonia is characterized by plugs of granulation tissue in the air spaces distal to and including the terminal bronchioles, associated with lymphocytic infiltration within well-preserved bronchiolar walls and the surrounding lung interstitium. Organizing pneumonia has a very different profile from the entity of bronchiolitis obliterans (also found in RA), with a clinical presentation of pneumonia (as opposed to airflow obstruction), multifocal consolidation on chest radiograph and CT (see [Figure 65-3B](#)), a restrictive functional defect, and a much higher chance of responsiveness to corticosteroids than bronchiolitis obliterans (with a good outcome in 15 of the first 17 reported cases).¹³⁸ Organizing pneumonia is more common in RA than in other CTDs (with the exception of inflammatory myopathy and mixed connective tissue disease). In a series of 40 patients with RA undergoing open-lung biopsy, organizing pneumonia (6 cases) had a prevalence similar to that of interstitial fibrosis (5 cases),¹³⁹ although organizing pneumonia might have been overrepresented owing to an acute presentation (and thus a perceived need to reach a definitive histologic diagnosis). The good prognosis generally seen in organizing pneumonia has been emphasized in the medical literature, but a minority of RA patients with organizing pneumonia progress to respiratory failure and death despite treatment.

Bronchiolitis Obliterans

Bronchiolitis obliterans (BO) in RA has now been described in numerous case reports and small series. BO (synonymous with obliterative bronchiolitis and constrictive bronchiolitis) is characterized histologically by destruction of the bronchiolar wall by granulation tissue, effacement of

the lumen, and eventual replacement of the bronchiole by fibrous tissue. There is circumstantial evidence to suggest that, in some cases, BO may be preceded by an inflammatory exudate; prominent bronchiolar inflammation may be found in patients with the shortest symptomatic course.¹⁴⁰ The expression of HLA antigens B40 and DR1 is increased in BO associated with RA (but not in isolated BO).¹⁴¹

In early descriptions, the hallmark of BO was a rapidly progressive, often fatal, course; however, because clinician awareness of the disease was then low, patients with advanced and progressive disease were undoubtedly overrepresented. There is great heterogeneity in the speed of progression, with some patients having indolent disease¹⁴²; the use of CT in RA patients with suspected pulmonary complications has now identified a subgroup with occult bronchiolitis (see [Fig. 65-3C](#)), often admixed with ILD. The prevalence of unsuspected BO in unselected RA patients remains uncertain, with unexplained airflow obstruction identified in a significant minority (including many nonsmokers) in one study¹⁴³ but no increase in the prevalence of pulmonary function abnormalities suggestive of isolated small airway disease in two subsequent controlled series.^{144,145}

Two major associations with the development of BO in RA have been reported. It is likely that secondary Sjögren syndrome is an important predisposing factor, being associated with BO in five of six RA patients in one series¹⁴²; the spectrum of histologic abnormalities in these cases, ranging from peribronchiolar lymphocytic infiltration to small airway destruction, was analogous to changes seen in the parotid gland in Sjögren syndrome. As the presence or absence of Sjögren syndrome is not documented in many case reports of BO in RA, the etiologic importance of Sjögren syndrome in this context remains uncertain.

More contentious is the reported association between BO and the use of penicillamine, first reported in the late 1970s.¹⁴⁶ After a number of case reports and small series, a significantly higher prevalence of BO was identified in RA patients who took penicillamine (3 of 133) than in other RA patients (0 of 469) in a large cohort.¹⁴⁰ It is possible that the development of BO and the use of penicillamine are both markers of more aggressive RA and are linked for this reason; however, BO developed less than 1 year after penicillamine was begun in 19 of the first 20 cases,¹⁴⁰ and thus the association is unlikely to be entirely spurious. Because BO has been reported in many RA patients not taking penicillamine, it is likely that an underlying predisposition to BO in RA is unmasked by penicillamine (which disrupts collagen linkage and thus interferes with tissue repair). A relationship between BO and gold therapy has been suggested but is not endorsed by recent clinical experience.

Follicular Bronchiolitis

Follicular bronchiolitis (FB) is characterized by external compression of bronchioles by hyperplastic lymphoid follicles, with variable lymphocytic infiltration of the bronchiolar wall ([eFig. 65-5B](#)). FB is associated more commonly with RA than with other CTDs¹⁴⁷ and is often found incidentally at lung biopsy in RA patients with interstitial pulmonary fibrosis. No causative mechanism has been identified, and it is unclear whether FB predisposes to the subsequent development of BO. When found in isolation, FB simulates ILD,

with reticular or nodular opacities on chest radiography and a pattern of functional impairment that may be restrictive or obstructive. Clinically significant isolated FB is rare in RA, but its recognition is important because a response to corticosteroid therapy, although not the rule, is much more likely than in BO; in six of the first nine reported cases, disease stabilized or regressed with treatment.¹³⁸ In a CT study of patients with histopathologically proven FB, the most prominent features were centrilobular (see Fig. 65-3D and E) and peribronchial nodules together with patchy ground-glass increases in attenuation in a bronchocentric distribution.¹⁴⁸

Bronchiectasis

The prevalence of bronchiectasis is higher in RA than in other CTDs. One literature review identified 289 patients with bronchiectasis associated with RA reported since 1928; however, because respiratory symptoms preceded the systemic manifestations of RA in 90%, it is likely that chance association accounts for a high proportion of early reported cases.¹⁴⁹ Although associated with long-standing RA in one study,¹⁵⁰ on prospective evaluation of 50 RA patients, bronchiectasis was present on 30% of CT scans (see Fig. 65-3F and G).¹⁵¹ Bronchiectasis in RA is not associated with more aggressive systemic disease and is often clinically silent, with little or no sputum production and a less progressive and disabling course than in patients with idiopathic bronchiectasis.

Pulmonary Vasculitis

It is surprising that pulmonary vasculitis is reported only rarely in RA, given the relatively high prevalence of systemic vasculitis in the disease. Pulmonary hypertension resulting from pulmonary vascular disease (as opposed to extensive pulmonary fibrosis) is uncommon, although occasional cases of pulmonary vasculitis have been found at autopsy.¹⁴⁷ Similarly, diffuse alveolar hemorrhage is a rare complication of RA.

Pulmonary Rheumatoid Nodules

Pulmonary rheumatoid nodules may be single or multiple, are found on chest radiography in less than 1% of RA patients,¹¹⁵ and are usually associated with rheumatoid nodules elsewhere in the body.¹⁵² Occasionally pulmonary rheumatoid nodules precede the development of systemic disease. Nodules are circumscribed, with central necrotic material contained by palisading epithelioid cells and surrounded by fibrosis and lymphocytic infiltration (eFig. 65-5C). Nodule cavitation occasionally causes hemoptysis, and pneumothorax may result from the rupture of subpleural nodules. Diffuse infiltration by small nodules leading to respiratory failure has been reported.¹⁵³ However, nodules generally present as asymptomatic abnormalities on imaging (see Fig. 65-3H-J) and may vary in size according to underlying rheumatoid activity; thus, when solitary, their growth as judged by chest radiography may simulate malignancy. Caplan syndrome consists of the association of single or multiple nodules with coal workers' pneumoconiosis, which is often trivial, in keeping with the suggestion that nodule formation results from a hypersensitivity reaction to inhaled coal dust perhaps amplified by immunologic overactivity.

Pleural Disease

Pleural disease is seen at autopsy in approximately 50% of patients,¹¹⁵ and 20% give a history of pleuritic chest pain¹⁵⁴ (eFig. 65-5D). However, pleural effusions are found in less than 5%,^{113,114} usually in men,¹⁵² and are frequently asymptomatic, often being identified on routine chest radiography. In a minority, pleuritic pain and fever are prominent, and the exclusion of empyema (which may be more prevalent in RA) is required. Occasionally, effusions may develop acutely in association with pericarditis or exacerbations of arthritis; more typically, radiographic abnormalities are chronic, often remaining unchanged for years. The fluid is an exudate, with a low glucose level (correlating poorly with serum glucose),¹⁵⁵ a low pH, and usually, a predominant lymphocytosis (although a neutrophilia is occasionally found). Pleural fluid rheumatoid factor levels tend to mirror serum levels and have little independent diagnostic value.

Other Pulmonary Complications

Other pulmonary complications of RA are rare. Lymphocytic interstitial pneumonia is an occasional finding at lung biopsy¹³⁹ and responds variably to corticosteroid therapy. Apical fibrosis mimicking the lung disease of ankylosing spondylitis has been reported.¹⁵⁶ Extensive apical cavitation in the absence of nodules or other causes of fibrocavitary disease (including tuberculosis) has been described in a handful of cases and may follow a fulminant course.¹⁵⁷ Pulmonary amyloidosis has been reported occasionally. The incidence of secondary pulmonary hypertension increases with time from diagnosis.¹⁵⁸ Lower respiratory tract infection is increased in frequency in RA; bronchopneumonia is a common terminal event, accounting for 15% to 20% of deaths in RA patients.^{159,160} An increase in lung cancer has been reported in RA patients.¹⁶¹

Drug-Induced Pulmonary Disease

Drug-induced pulmonary disease is a particular problem in RA because of the widespread use of methotrexate in routine clinical practice, and lung disease has been reported in 3% to 18% of RA patients treated with methotrexate.^{162,163} Methotrexate pneumonitis is potentially life threatening. It presents with cough, dyspnea, fever, widespread crackles, and pulmonary opacities on chest radiography and CT (see eFig. 71-4), which may be focal or diffuse.¹⁶⁴ Although the presentation is sometimes explosive, more often, the onset is subacute (with symptoms evolving for up to 2 months before diagnosis)¹⁶⁴; 50% of cases are diagnosed within 4 months of initiation of methotrexate therapy. Because the clinical and radiographic features are nonspecific, methotrexate-induced lung disease should always be suspected in the treated patient presenting with progressive lung disease. Unfortunately, histologic findings are nonspecific, although finding a prominent lymphocytic infiltration increases the likelihood of methotrexate pneumonitis.¹⁶⁵ There is conflicting evidence on whether preexisting lung disease predisposes to lung injury caused by methotrexate, but the published evidence does not suggest that functional impairment is an absolute contraindication to its use (although particular caution is warranted when pulmonary reserve is grossly compromised, and patients with previous methotrexate toxicity should

not be retreated).^{164,166} Pulmonary methotrexate toxicity is associated with a mortality rate of 15% to 20%¹⁶⁴; because the lymphocytic component of disease is wholly or partially reversible, immediate withdrawal of methotrexate and the early institution of steroid therapy are warranted.

Pulmonary toxicity in RA has also been documented with sulfasalazine, gold therapy, and penicillamine (discussed earlier; see Chapter 71). Pulmonary opacities (due to organizing pneumonia) associated with sulfasalazine most commonly present in the upper lobes; this side effect is rare in RA, with only a handful of cases reported (most cases were reported in ulcerative colitis).¹⁶⁷ Pulmonary disease induced by gold takes the form of alveolar opacities adjacent to bronchovascular bundles, best demonstrated by high-resolution CT, and often associated with fever or skin rash, relatively low rheumatoid factor titers, and a BAL lymphocytosis.¹⁶⁸ In most patients with sulfasalazine or gold toxicity, lung disease largely regresses with withdrawal of the agent and corticosteroid therapy.

There have been a number of reports of rapidly progressive ILD associated with anti-TNF- α therapies, including etanercept and infliximab, although there are divergent views on whether these reports are truly indicative of drug toxicity or reflect the selective use of these therapies in more aggressive RA. The range of reported toxicity ranges from infection (with particular focus on reactivation of tuberculosis), undoubtedly a true association, to interstitial disease and vasculitis.^{169,170} Leflunomide has also been associated with pulmonary rheumatoid nodules and interstitial disease.^{171,172}

Acute Exacerbations of Interstitial Lung Disease

Acute exacerbations of ILD, representing the development of diffuse alveolar damage, are less prevalent in CTD than in idiopathic pulmonary fibrosis. In both settings, presenting features include worsening dyspnea over 2 to 4 weeks, new ground-glass opacities on HRCT (eFig. 65-6), and the absence of infection or other overt causes of decline.¹⁷³ Acute exacerbations are more common in RA than in other CTDs (see eFig. 65-6), with a high early mortality.¹⁷⁴⁻¹⁷⁶ Triggers of acute exacerbations have not been identified in RA and there is currently no proven therapy, although high-dose corticosteroid therapy is usually given.

PULMONARY FUNCTION TESTS

Patterns of functional impairment in RA have been variable in unselected populations, with predominant airflow obstruction a frequent finding in one cohort¹⁴³ but reductions in DL_{CO} ascribed to occult interstitial fibrosis in at least 40%.¹³¹ Inconsistencies in published data can be ascribed to the confounding effects of smoking and variations in the type and severity of associated pulmonary disease. Airflow obstruction may result from bronchiectasis or BO. Interstitial pulmonary fibrosis, organizing pneumonia, and lymphocytic interstitial pneumonia give rise to restrictive defects.

RADIOLOGIC FEATURES

In chest radiographic series of unselected patients with RA, appearances indicative of ILD are found in 1% to 5% of

cases.^{113,114,132,135} In interstitial pulmonary fibrosis, appearances are indistinguishable from idiopathic pulmonary fibrosis in a minority of cases, with symmetrical basal interstitial opacification in limited disease and diffuse coarse reticular abnormalities in extensive disease. In the majority of cases, CT appearances are intermediate between those of idiopathic pulmonary fibrosis (see Fig. 65-3A) and nonspecific interstitial pneumonia or are suggestive of the latter pattern.¹⁷⁷ Ground-glass opacity, consisting of a patchy or diffuse increase in lung density, is likely to denote inflammatory histologic appearances or fine intralobular fibrosis, as in other fibrosing lung diseases. Rheumatoid nodules (see Fig. 65-3H-J) are usually radiologically discrete and small but are often multiple and may reach up to 7 cm in diameter; in Caplan syndrome, nodules appear in crops, often grow rapidly, and may cavitate. Other chest radiographic findings in RA include focal consolidation (in organizing pneumonia [see Fig. 65-3B], infectious pneumonia, and lung disease induced by methotrexate); focal areas of hyperinflation (in BO [see Fig. 65-3C]); and pleural thickening or effusion.

The cardinal CT feature of organizing pneumonia is patchy bilateral air space consolidation (often with associated ground-glass attenuation), which is often predominantly subpleural¹⁷⁸ but may have a bronchovascular distribution (see Fig. 65-3B).¹⁷⁹ Small nodules (≤ 1 cm in diameter) are common in organizing pneumonia; small pleural effusions and limited fibrosis (probably resulting from prolonged untreated inflammation) are occasional findings.

In bronchiolitis, bronchiolar structures are occasionally visualized directly on CT as centrilobular (see Fig. 65-3D and E), micronodular opacities and peripheral branching structures, denoting marked thickening of the bronchiolar wall; this appearance may be most frequent in FB.¹⁸⁰ In BO, areas of reduced lung density in a patchy distribution ("mosaic perfusion," see Fig. 65-3C) are associated with a reduction in the caliber of pulmonary vessels in areas of decreased attenuation, indicative of regional hypoxic vasoconstriction in areas of severe bronchiolitis. Bronchiectasis and bronchial wall thickening on CT are common in constrictive bronchiolitis.

TREATMENT OF PULMONARY COMPLICATIONS

The treatment of ILD has usually consisted of corticosteroid therapy, with or without immunosuppressive agents. However, when CT appearances are similar to those of idiopathic pulmonary fibrosis, immunomodulation, and especially high-dose corticosteroid therapy, should be used with caution due to the recent documentation of major toxicity with this approach in idiopathic pulmonary fibrosis.¹⁸¹ It can reasonably be argued that in this context high-dose steroid therapy should be largely confined to those with suspected supervening drug-induced lung toxicity or diffuse alveolar damage. Owing to small numbers, regimens have remained anecdotal. Organizing pneumonia and methotrexate pneumonitis often respond well to treatment. Regression of disease is highly variable in FB and lymphocytic interstitial pneumonia and is virtually never seen in BO. Lung function may improve in response to treatment in interstitial pulmonary fibrosis, but a more realistic goal

Table 65-6 Systemic Lupus Erythematosus**CRITERIA FOR DIAGNOSIS***

Malar rash
 Discoid rash
 Photosensitivity skin rash
 Oral or nasopharyngeal ulceration
 Nonerosive arthritis involving ≥ 2 peripheral joints
 Serositis (pleuritis or pericarditis)
 Renal disorder (persistent proteinuria or cellular casts)
 Neurologic disorder (unexplained seizures or psychosis)
 Hematologic disorder (hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia)
 Immunologic disorder (positive LE cell, anti-DNA antibody, anti-Sm antibody, false-positive syphilis serology)
 Elevated antinuclear antibodies

LUNG MANIFESTATIONS

Acute lupus pneumonitis
 Interstitial pulmonary fibrosis
 Pulmonary vasculitis
 Diffuse alveolar hemorrhage
 Pulmonary hypertension
 Shrinking lung syndrome
 Antiphospholipid antibody syndrome
 Organizing pneumonia
 Pleural disease

*Minimum of 4 criteria required.
 LE, lupus erythematosus.

in most cases is to prevent further progression of disease, especially when lung disease is extensive.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is an inflammatory multisystem disorder of unknown etiology with protean clinical and laboratory manifestations and a variable course and prognosis. The 1982 revised American College of Rheumatology criteria for the diagnosis of SLE require that a minimum of four of the criteria listed in Table 65-6 be satisfied (although SLE is sometimes diagnosed with fewer than four criteria).¹⁸²

EPIDEMIOLOGY AND RISK FACTORS

SLE appears throughout the world; the reported prevalence ranges from 12 to 50/100,000 population, and the incidence ranges from 1.8 to 7.6/100,000 population/yr.¹⁸³ There is a six- to ten-fold female excess, and the disease is three times more common in African Americans than in whites. The 5-year survival rate exceeds 90%, but the mortality rate is three times higher than in the general population. Support for a genetic contribution to disease includes a high prevalence in monozygotic twins, familial clustering, and associations among SLE and HLA-DR2, HLA-DR3, and the C4A null allele.¹⁸⁴ No infectious or other environmental factor has been shown to play a major etiologic role.

PULMONARY MANIFESTATIONS

Pleuropulmonary manifestations of SLE are listed in Table 65-6.

Diffuse Lung Disease

Diffuse lung disease on lung biopsy or at autopsy has been reported in 4%, 33%, and 70% of SLE patients.¹⁸⁵⁻¹⁸⁷ These striking inconsistencies undoubtedly reflect major variations in the histologic diagnostic criteria. In the series with the highest prevalence, trivial interstitial thickening was categorized as “pulmonary fibrosis” but likely represented the minor residuum of infection or inflammatory complications of SLE. Only 3% of SLE patients have clinical evidence of diffuse lung disease at the onset of systemic disease, and a disease resembling interstitial pulmonary fibrosis (eFig. 65-7) develops during follow-up in less than 5%.¹⁸⁸ Risk factors for pulmonary fibrosis in SLE include increasing age, pneumonitis, and anti-RNP antibodies.¹⁸⁹

Interstitial Pneumonia. The clinical presentation (dyspnea, cough, predominantly basal crackles, a restrictive lung function defect or isolated reduction in DL_{CO} , basal opacities on chest radiography) is similar to idiopathic pulmonary fibrosis. Features not typical of idiopathic pulmonary fibrosis include variably associated pleuritic pain, a paucity of patients with morphologically extensive or functionally severe lung fibrosis, and the frequent presence of enlarged peribronchiolar lymphoid follicles at lung biopsy (although other histologic findings are similar to usual interstitial pneumonia). Partial regression of disease with corticosteroids in 9 of 14 cases in one series¹⁹⁰ suggests that an empirical trial of therapy is usually warranted.

Acute Lupus Pneumonitis. Although seen in less than 2% of SLE patients, acute lupus pneumonitis is often life threatening, with a mortality rate of more than 50% (once respiratory failure has supervened) despite treatment.¹⁹¹ The predominant histologic feature of diffuse alveolar damage is nonspecific, and it has been argued that acute lupus pneumonitis is merely a manifestation of aspiration or bacterial infection.¹⁸⁵ However, well-documented striking responses to corticosteroids and immunosuppressive agents after antibiotic failure suggest strongly that the disorder is a true, albeit rare, entity.

Acute lupus pneumonitis is not to be confused with organizing pneumonia, discussed elsewhere in this chapter and reported in only a handful of adult patients with SLE, or with lymphocytic interstitial pneumonia, described in a small number of patients with SLE.

Extrapulmonary Restriction

Extrapulmonary restriction, resulting in exertional dyspnea, a restrictive functional defect, and marked decrease of DL_{CO} , is a well-recognized complication of SLE. The “shrinking lung syndrome” was first described in patients with severe restriction and a marked reduction in lung volume on chest radiography, and it is generally ascribed to diaphragmatic weakness (Fig. 65-4).¹⁹² However, the use of sniff pressures to evaluate diaphragmatic strength may be confounded by concurrent lung restriction or airflow obstruction; in one study, with the use of alternative methods to evaluate diaphragmatic function, the characteristic restrictive defect was attributed to an “unspecified restriction in chest wall expansion.”¹⁹³ No treatment of proven efficacy currently exists, although a handful of patients have improved in

Figure 65-4 Systemic lupus erythematosus. **A**, Chest radiograph from a patient with systemic lupus erythematosus shows marked elevation of both hemidiaphragms, in keeping with “the shrinking lung syndrome.” **B**, On a CT scan from the same patient as in **A**, linear abnormalities are seen that denote subsegmental atelectasis resulting from regional hypoventilation (due to diaphragmatic weakness). The heart is enlarged.

association with corticosteroid or immunosuppressive therapy.¹⁹⁴ The disorder is almost always self-limited, although sometimes it is severe.

Diffuse Alveolar Hemorrhage (see Chapter 67)

Although seen more frequently in SLE than in other CTDs, diffuse alveolar hemorrhage is rare in SLE. The typical presentation of acute dyspnea and extensive pulmonary opacities on imaging (eFig. 65-8, see eFig. 67-4) may mimic acute lupus pneumonitis, especially in the absence of hemoptysis.¹⁹⁵ Diffuse alveolar hemorrhage is often life threatening, with a mortality rate of approximately 50%, similar to that of acute lupus pneumonitis; however, because the two diseases are both treated empirically with corticosteroid and immunosuppressive therapy, the important differential diagnosis is opportunistic infection. Patients with SLE have underlying defects in most arms of the immune system and are at added risk of fulminant infection with the use of corticosteroids or immunosuppressive agents.¹⁹⁶ In this context, a misdiagnosis of acute lupus pneumonitis or diffuse alveolar hemorrhage may lead to a potentially disastrous increase in immunosuppression. Thus, the performance of BAL to exclude opportunistic infection may be crucial in SLE patients with unexplained extensive pulmonary opacities. Treatment responses in both acute lupus pneumonitis and diffuse alveolar hemorrhage have been observed with intravenous immunoglobulins, plasmapheresis, and rituximab.¹⁹⁷⁻¹⁹⁹

Pulmonary Hypertension

Pulmonary hypertension was once considered rare in SLE, but it is now reported with increasing frequency²⁰⁰ and has a 2-year survival rate of less than 50% in severe disease. Abnormalities indicative of subclinical pulmonary hypertension are found on echocardiography in 10% of SLE patients, usually in association with Raynaud phenomenon,²⁰¹ and thus, it is likely that, in many cases, pulmonary hypertension results from vasoconstriction rather than pulmonary vasculitis (which is seldom identified in SLE); in autopsied patients with pulmonary hypertension, overt vasculitis is rare (see also Chapter 58).

Important alternative mechanisms for pulmonary hypertension include vasculitis and thromboembolism.²⁰² Thromboembolism has a high prevalence in SLE, especially in patients with antiphospholipid antibodies (which cross-react with coagulation factors).^{203,204} In a 1993 study of 842 SLE patients, immunoglobulin G anticardiolipin antibodies were present more frequently than immunoglobulin M antibodies (24% vs. 13%), but both were associated with a 30% prevalence of thrombosis (as opposed to 10% in other SLE patients).²⁰⁵ Patients with antiphospholipid antibody syndrome also have a higher incidence of impaired lung function than normal controls.²⁰⁶ In view of the multiplicity of mechanisms potentially responsible for pulmonary hypertension, vasodilators and anticoagulation have all been advocated empirically for patients with the pulmonary vascular disease of SLE. Corticosteroid or immunosuppressive agents may be effective therapy for SLE-associated pulmonary hypertension.²⁰² In a small series of patients given chronic epoprostenol, measures of pulmonary hypertension, pulmonary vascular resistance, and exercise capacity all improved.²⁰⁷

Pleural Disease

Pleural disease is the most common pulmonary manifestation of SLE. Clinical or radiographic evidence of pleural involvement is seen in 20% of patients at the onset of systemic disease and in at least 50% at some time²⁰⁸ (with pleural abnormalities at autopsy in 50% to 100%). Pleural disease is often asymptomatic, but pleuritic pain may be recurrent or intractable. Pleural fluid is usually serosanguineous (but occasionally hemorrhagic) and exudative, with a neutrophilia in patients with pleurisy but a predominant lymphocytosis in chronic effusions.²⁰⁸ The nonspecific histologic appearance of fibrinous pleuritis is not diagnostically useful. The identification of lupus erythematosus cells has largely fallen out of favor because technical difficulties greatly reduce the sensitivity of the test in confirming that a pleural effusion is due to SLE.²⁰⁹ The measurement of pleural fluid antinuclear antibody titers may be more diagnostically useful when the etiology of pleural disease is in doubt²¹⁰ (see also Chapter 79).

SJÖGREN SYNDROME

Sjögren syndrome is an autoimmune disorder characterized by lymphocytic infiltration of the lacrimal, salivary, conjunctival, and pharyngeal mucosal glands, with variable involvement of extraglandular tissue. The cardinal clinical features of keratoconjunctivitis sicca (dry eyes) and xerostomia (dry mouth) may exist in isolation (primary Sjögren syndrome, typically seen in women older than age 40) but are more often associated with CTDs such as RA, SSc, or SLE (secondary Sjögren syndrome). Sicca symptoms are common in lung disease, however, and need to be carefully evaluated.²¹¹ Variable diagnostic criteria are used internationally; in one proposed diagnostic algorithm, sicca symptoms are mandatory, with supportive evidence including ocular signs (positive Schirmer test testing reduced tear formation, rose bengal score > 3 for staining of damaged conjunctiva and cornea), typical histologic appearances on salivary gland biopsy, antibodies to Ro (SS-A) or La (SS-B), or reduced salivary flow.²¹²

EPIDEMIOLOGY AND RISK FACTORS

The reported prevalence of primary Sjögren syndrome ranges from 0.5% to 3.0%. The etiology of the disease is unknown. Some evidence suggests a genetic predisposition, including familial clustering and an association with HLA-Dw2 and HLA-Dw3, but no environmental triggers have been identified.

PULMONARY MANIFESTATIONS

Pulmonary involvement is common in Sjögren syndrome. In early series, primary and secondary Sjögren syndromes were combined; it is likely that many of the pulmonary abnormalities seen in secondary Sjögren syndrome were ascribed to the underlying CTD. Careful evaluation of patients with primary Sjögren syndrome has shown that cough and dyspnea are common,²¹³ with objective evidence of pulmonary abnormalities in approximately one fourth of cases.²¹⁴ Lung involvement usually consists of lymphocytic infiltration similar to that seen in salivary glands and resulting in tracheobronchial disease or ILD, depending on whether involvement is limited to secretory glandular tissue or more widespread. However, population studies of respiratory involvement in Sjögren syndrome have been hampered by variations in diagnostic criteria, failure to discriminate between primary and secondary Sjögren syndrome, and failure to control for confounding features such as drug treatment and smoking. Lung manifestations include diffuse lung disease and tracheobronchial disease.

In a CT study of 35 patients, the most prevalent findings were large and/or small airway disease ($n = 19$) and diffuse lung disease ($n = 12$, including 7 in whom the features were suggestive of lymphocytic interstitial pneumonia). The patterns of physiologic abnormalities were consistent with the predominant CT pattern.²¹⁵

Diffuse Lung Disease

Although often asymptomatic, diffuse lung disease in Sjögren syndrome may present with cough, dyspnea,

crackles on auscultation, reticular or nodular opacities on chest radiography, and a restrictive pattern of functional impairment. Interstitial involvement can be classified as pulmonary fibrosis, lymphocytic interstitial pneumonia, or lymphoma (eFig. 65-9). Pulmonary fibrosis has been reported in up to 10% of patients with primary Sjögren syndrome²¹⁶ and most frequently takes the form of fibrotic nonspecific interstitial pneumonia (eFig. 65-9A).²¹⁷ Although a presentation typical of extensive or progressive interstitial pulmonary fibrosis is rare and interstitial disease in Sjögren syndrome is often regarded as clinically insignificant, Gardiner and coworkers²¹⁶ found that patients with primary Sjögren syndrome complaining of dyspnea ($\approx 10\%$) have a high prevalence of histologic abnormalities (fibrosis or lymphocytic infiltration) on transbronchial biopsy.²¹⁶ A 10-year follow-up study of 30 patients showed that most patients do not develop progressive lung disease, although the total gas transfer level fell significantly in seven cases.²¹⁸ In a recent report of 105 patients with primary Sjögren syndrome and diffuse lung disease, diagnosed between 1976 and 2005, there was a striking female preponderance (91%) and a twofold increase in mortality, compared with patients without lung involvement. Diffuse lung disease tended to develop early in the disease course with a cumulative incidence of 10% at 1 year after the diagnosis of systemic disease.²¹⁹

Lymphocytic interstitial infiltration may take the form of lymphocytic interstitial pneumonia, pseudolymphoma (extensive pulmonary lymphocytic infiltration with the formation of lymphoid follicles, eFig. 65-9E), or pulmonary lymphoma (eFig. 65-9F and G). Lymphocytic interstitial pneumonia, historically believed to be the most common diffuse lung disease in Sjögren syndrome,²²⁰ is characterized by a diffuse lymphocytic infiltrate, with or without histiocytes and multinucleated giant cells, most prominent around bronchioles. Regression of disease with corticosteroids, in isolation or in combination with immunosuppressants, is highly variable. There are recent anecdotal reports of responses to rituximab. Pseudolymphoma, characterized by pulmonary infiltration, may regress spontaneously and often responds well to corticosteroid therapy; however, some patients progress to pulmonary lymphoma. The prevalence of lymphoma is increased 40- to 50-fold in Sjögren syndrome²²¹; pulmonary lymphoma has a highly variable clinical and radiographic presentation, with the spectrum of disease ranging from diffuse interstitial involvement to discrete (often perihilar) masses (eFig. 65-9F and G).

Organizing pneumonia has been reported in Sjögren syndrome (eFig. 65-9D) but is less common than in RA or polymyositis. A response to corticosteroid therapy is usual but not invariable.

Tracheobronchial Disease

Tracheobronchial disease may take the form of loss of mucous secretion in the trachea (xerotrachea), chronic bronchitis, or small airway disease. Xerotrachea develops in up to 25% of patients with primary Sjögren syndrome and consists of atrophy of tracheobronchial mucous glands in association with a lymphoplasmacytic infiltrate, manifesting clinically as a relentless dry cough and endobronchial inflammation at bronchoscopy.²²² It is likely that similar histologic abnormalities in bronchi and bronchioles account

for an increased prevalence of bronchial hyperresponsiveness, reported in 40% to 60% of patients with primary and secondary Sjögren syndrome.²²³

Subclinical bronchiolitis may be common in Sjögren syndrome. In the ILD of Sjögren syndrome, lymphocytic infiltration is more prominent around small bronchioles, resulting in a BAL lymphocytosis²²⁴; thus, it is likely that the occasional cases of isolated lymphocytic bronchiolitis, presenting with a clinical picture of COPD, represent a more limited form of lymphocytic infiltration. The evaluation of airflow at low lung volumes in unselected patients with primary and secondary Sjögren syndrome has demonstrated a high prevalence of small airway dysfunction²¹³; aerosol penetration from central airways to the lung periphery is reduced, indicating small airway obstruction.²²⁵ These abnormalities, indicating either BO or mucous plugging, may contribute to an increased prevalence of bronchopneumonia but do not evolve into severe BO (which is not generally a feature of Sjögren syndrome, except in occasional cases with associated RA). FB has been reported in a handful of patients with primary Sjögren syndrome but may be more frequently seen in secondary Sjögren syndrome; in a number of reported cases of FB associated with RA, the presence of Sjögren syndrome is not explicitly excluded. FB and diffuse bronchiolar lymphocytic infiltration may be part of the same spectrum of disease, but the relationship between the two disorders is uncertain.

POLYMYOSITIS AND DERMATOMYOSITIS

The defining criteria for *polymyositis* (PM) and *dermatomyositis* (DM) are listed in Table 65-7. For PM, a definite diagnosis is made if the first four features are present, a probable diagnosis is made if any three of the first four features are present, and a possible diagnosis is made if any two of the first four features are present. For DM, the typical rash must be present, plus any three of the first four for a definite diagnosis, two of the first four for a probable diagnosis, and one of the first four for a possible diagnosis (Bohan and Peter's criteria).²²⁶

The skin problems of DM include the presence of scaly cutaneous eruptions affecting extensor surfaces of the finger joints (Gottron tubercles or papules) (Fig. 65-5A) and

Figure 65-5 Skin changes seen in dermatomyositis. **A**, Gottron papules. A discrete scaly rash is seen over the extensor surfaces of the joints. **B**, Heliotrope rash. Named after a lilac-like flower with purple petals, this purplish rash and associated edema particularly involve the eyelids. (Adapted from Iaccarino L, Ghirardello A, Bettio S, et al: The clinical features, diagnosis and classification of dermatomyositis. *J Autoimmun* 48–49:122–127, 2014, Fig. 1.)

the characteristic edema and violaceous or purplish, heliotrope rash that involves and surrounds the eyelids (see Fig. 65-5B). Proximal muscle weakness tends to be insidious, progressive, and painless, affecting head, neck, and limb girdles and eventually involving the muscles of the tongue and pharynx and the respiratory muscles. Pulmonary complications arise in approximately 45% of patients and are the most frequent cause of death.

EPIDEMIOLOGY AND RISK FACTORS

The inflammatory myopathies are relatively rare, affecting 2 to 10/100,000 population, with a female-to-male predominance of 2.5:1 and with a bimodal age distribution peaking in childhood and in the fourth to fifth decades. DM appears to have a higher expression of HLA-B8/DR3, HLA-B14, and HLA-B40, whereas PM associates with HLA-B8/DR3 and in African Americans with HLA-B7 and HLA-DRw6.²²⁷ There are multiple manifestations of lung disease, as listed in Table 65-7. The presence of diffuse lung disease has been associated with two HLA haplotypes: HLA-DRB1*1302-DQA1*0102-DQB1*0604 and HLA-DRB1*0405-DQA1*03-DQB1*0401.²²⁸ In combined series, the prevalence of diffuse lung disease can be up to 64%. The disease may also present with pulmonary symptoms, and, in one series, this was the case in 21 of 70 patients.²²⁹ The

Figure 65-6 Organizing pneumonia in polymyositis. **A**, CT scan shows dense consolidation that denotes organizing pneumonia in a patient with polymyositis. As shown in this example, the disease tends to be most prominent posteriorly in the lower lobes. **B**, After treatment, the dense consolidation has regressed, but there is extensive residual linear opacification, representing residual fibrosis and resulting in traction bronchiectasis on the right and a restrictive functional defect. (Courtesy Michael Gotway, MD.)

prevalence of lung disease varies from series to series, and often the respiratory symptoms are masked by muscle fatigue. Nonetheless, pulmonary complications of the disease can be a frequent cause of death.

PULMONARY MANIFESTATIONS

Diffuse Lung Disease

Diffuse lung disease is the most common problem encountered in the context of DM with PM and may develop in up to 32% of patients.²³⁰ The prevalence of diffuse lung disease may be less common in patients with amyotrophic DM, a small subgroup of patients with the rash of DM but not the muscle involvement, and is three to five times more common in women than men, most commonly presenting in the fifth decade. The natural history and treated course of diffuse lung disease often mimics that of idiopathic fibrotic nonspecific interstitial pneumonia and, in many cases, a major component of organizing pneumonia, admixed with fibrotic abnormalities, is a prominent early feature, both histologically and on HRCT²³¹⁻²³³ (Fig. 65-6). However, in a distinct minority of cases with supervening diffuse alveolar damage (eFig. 65-10), the onset is subacute, rapidly progressive, and often resistant to treatment.²³⁴ The histopathologic features associated with these forms of presentation include nonspecific interstitial pneumonia and usual interstitial pneumonia in patients with an interstitial pulmonary fibrosis pattern, diffuse alveolar damage in the acute pneumonitis, and organizing pneumonia.²³⁵⁻²³⁷ In a large series of 70 patients, Douglas and colleagues²²⁹ reported that 82% of patients who were biopsied had the nonspecific interstitial pneumonia pattern of histopathology. One report described an acute presentation of pulmonary capillaritis with alveolar hemorrhage in association with PM.²³⁸

Clinical Features. The clinical features of diffuse lung disease in PM with DM depend on the nature of the lung process. Dyspnea and nonproductive cough are the most common presenting symptoms. Breathlessness on exertion without wheeze is common and, if the myopathy is severe, orthopnea may be striking. Hemoptysis may develop if there is capillaritis. Pleural disease is uncommon. Pulmonary involvement can develop before the systemic disease or at any time in the disease course. There is no correlation

between the severity of pulmonary parenchymal involvement and the systemic musculoskeletal manifestations. Rarely, patients present acutely with or progress rapidly to acute respiratory failure.

Imaging. Chronic diffuse lung disease is associated with peripheral reticular opacities, particularly in the lung bases as for interstitial pulmonary fibrosis. Acute pneumonitis can result in ground-glass opacification on chest radiography and alveolar hemorrhage with areas of consolidation.

High-resolution CT is more sensitive and specific than chest radiography, highlighting the distributions of the different processes. CT findings include thickened interlobular septa, linear opacities, ground-glass opacification (see eFig. 65-10), and patchy consolidation. A combination of consolidation with a peripheral reticular pattern is highly characteristic.²³⁹ Traction bronchiectasis and honeycombing are less common. The consolidation may evolve into a reticular pattern.²⁴⁰ DM and PM are well-recognized paraneoplastic phenomena, so it is sometimes difficult to determine which condition presented first.²⁴¹ Screening for occult carcinoma is recommended with mammography, abdominal CT, pelvic ultrasonography, and tumor markers.

Pulmonary Function. Lung function tests show a restrictive ventilatory defect with reduced gas transfer. In recent hemorrhage or marked myopathy, there may be a disproportionate preservation of the DL_{CO} . However, it must be remembered that acute hemorrhage can present in the context of previous chronic disease, so the DL_{CO} may be normal or subnormal but elevated from a level that was previously lower. Severe reduction in DL_{CO} is associated with increased mortality.

Bronchoalveolar Lavage. BAL lymphocytosis and neutrophilia have been described in diffuse lung disease associated with DM/PM. The significance of BAL is debated, but it appears that neutrophilia on BAL is associated with clinical deterioration.²⁴²

Laboratory Tests. Several studies have reported no association between creatine kinase levels and respiratory disease. In fact, the presence of a low creatine kinase has been associated with more rapidly progressive diffuse lung disease.^{243,244} Studies of autoantibodies have highlighted

the association between the presence of antibodies to aminoacyl-transfer RNA (tRNA) synthetases, inflammatory myopathies, and diffuse lung disease.²⁴³ These antibodies help define the clinical antisynthetase syndrome: the coexistence of myositis, diffuse lung disease, and arthritis. The most common autoantibody is Jo-1 (a cytoplasmic antihistidyl tRNA synthetase), found in 20% to 30% of patients with inflammatory myopathy and correlating strongly with the presence of diffuse lung disease. Jo-1 antibodies are present in 50% to 100% of cases of inflammatory myopathy and diffuse lung disease, in contrast to less than 5% of patients without diffuse lung disease. A variety of novel autoantibodies have been described with affinity for other tRNA synthetase molecules: PL-12, PL-7, EJ, OJ, and Ku.²⁴⁵

Other Pulmonary Manifestations

Muscular weakness may lead to aspiration pneumonia in up to 20% of patients and is usually associated with dysphagia. Respiratory muscle weakness and hypercapnic respiratory failure develop in up to 25% of patients, although severe respiratory failure requiring ventilatory support is less common. Bilateral diaphragmatic paralysis has been reported.

Treatment of Pulmonary Complications

Diffuse lung disease is a serious complication of DM/PM and is associated with increased mortality.²⁴⁶ The clinical course and prognosis of DM/PM-associated diffuse lung disease is heterogeneous and depends on the histologic pattern of disease. The decision to treat and the choice of therapy, therefore, need to be individualized. Corticosteroids are the preferred initial therapy. Oral prednisolone (0.75 to 1 mg/kg/day) is usual, but intravenous corticosteroids are required in more severe or rapidly progressive disease. Immunosuppressive therapy may be used in patients who are steroid resistant or experiencing adverse effects from corticosteroids. There are some reports of efficacy of cyclophosphamide,^{247,248} cyclosporine A,²⁴⁹ and azathioprine.^{250,251} In refractory cases, methotrexate and intravenous immunoglobulin should be considered. Mycophenolate has been shown to be safe and effective in treatment of the systemic disease, but no controlled studies have yet been performed in DM/PM-related lung disease. As discussed earlier, in pilot studies, rituximab is promising treatment for the anti-synthetase syndrome,²⁵² including for patients with life-threatening disease refractory to other immunomodulatory therapies.²⁵³

MIXED CONNECTIVE TISSUE DISEASE

Mixed connective tissue disease (MCTD) is defined by the presence of features of SLE, SSc, and PM (Sjögren syndrome may also be seen) in association with high titers (>1:1600) of autoantibody directed against the extractable nuclear antigen U1-RNP.^{254,255} Criteria that have been suggested for the diagnosis of MCTD include the presence of antibody to the U1 ribonuclear protein together with the clinical features of hand edema, synovitis, Raynaud phenomenon,

acrosclerosis, and myositis. At least three of these clinical features are needed in addition to the autoantibody finding. A fourth clinical feature is required if the initial three are Raynaud phenomenon, edema, and acrosclerosis. The difference between MCTD and overlap syndrome may be semantic, but the former often presents more acutely and with greater specificity for U1-RNP. MCTD may differentiate into specific rheumatologic diseases. This differentiation may be genetically determined.²⁵⁶

Other overlap syndromes are reported in which clinical features of more than one CTD are present in the same patient. Although MCTD tissue disease remains the most clearly definable, other overlap syndromes are seen both with and without typical autoantibody association. Of the former, overlapping clinical features found in association with U2-RNP and U3-RNP and the tRNA synthetase-associated diseases (see earlier) can be considered to be part of an overlap syndrome. Antibodies to PM-Scl, KU, and U2-RNP are associated with overlaps of SSc and PM.²⁵⁵

The prevalence of MCTD is unclear, but it is estimated at 1 in 10,000, with a 9:1 female preponderance, most frequently presenting in the fourth decade. Pleuropulmonary complications are seen in 20% to 85% of patients, but diffuse lung disease (most commonly a nonspecific interstitial pneumonia CT pattern) is the most common lung complication.²⁵⁷ In a CT study of 41 patients, the major abnormalities were ground-glass opacities in all, subpleural micronodules in 40 of 41, and nonseptal linear opacities in 32 of 41.²⁵⁸ Pleural effusions develop in patients with other clinical features of SLE and are usually small, are exudative, and often resolve spontaneously. Pulmonary hypertension may also develop.²⁵⁹ Respiratory muscle weakness, diffuse alveolar hemorrhage, and small airway disease are less common complications.

Survival is difficult to quantify owing to the heterogeneity of disease. Individual disease course tends to be similar to that of the CTD most closely resembled in that patient. Survival is better if the diffuse lung disease is associated with U1-RNP positivity than with no U1-RNP. Treatment depends on the nature of the lung disease and is identical to the approaches used for the other CTDs. Pleural effusions are often responsive to corticosteroids. A combination of low-dose prednisolone and an immunosuppressant (such as cyclophosphamide or azathioprine) is generally used to treat interstitial fibrosis, with an approach similar to that for SSc.

UNDIFFERENTIATED CONNECTIVE TISSUE DISEASE

Up to 25% of patients with autoimmune features do not fulfill American College of Rheumatology criteria for a specific CTD, and a large proportion never progress to a “differentiated” CTD. ILD may complicate undifferentiated connective tissue diseases,²⁶⁰ with little known about the prognosis or treatment of ILD in this context. However, attention has recently focused on this patient subgroup²⁶¹ as CTD is eventually diagnosed in approximately 15% of patients presenting with idiopathic interstitial pneumonia^{262,263} and in 30% of patients with idiopathic NSIP.²⁶⁴

Figure 65-7 Relapsing polychondritis. **A** and **B**, Saddle nose deformity indicating loss of cartilage of the nose due to inflammatory deterioration of cartilage structure. In this 42-year-old man, destruction of the nasal septum led to restriction of ventilation with collapse of the internal nasal valves during a rapid inspiration. **C**, Relapsing polychondritis: chest radiographic appearance. Focused frontal chest radiograph shows smooth sagittal narrowing of the trachea (arrows). (**A** and **B**, From Haug MD, Witt P, Kalbermatten FD, et al: Severe respiratory dysfunction in a patient with relapsing polychondritis: should we treat the saddle nose deformity? *J Plast Reconstr Aesthet Surg* 62:e7–e10, 2009, Fig. 3; **C**, Courtesy Michael Gotway, MD.)

The view that all patients with idiopathic NSIP have undifferentiated CTD was based on findings in a small patient cohort, in which broad diagnostic criteria for undifferentiated CTD were used, including highly nonspecific features such as weight loss, gastroesophageal reflux, and a high erythrocyte sedimentation rate.²¹¹ However, with use of the more specific diagnostic criteria of Mosca²⁶⁵ in a subsequent larger retrospective series, criteria for undifferentiated UCTD were met in only 31% of patients with idiopathic NSIP and in 13% of patients with IPF.²⁶⁶ The presence of undifferentiated CTD had no effect on outcome in this series and in other reports of idiopathic interstitial pneumonia, the presence of antinuclear antibodies²⁶⁷ and the presence of a sign or symptom of CTD in combination with a non-specific autoantibody²⁶⁸ had no prognostic significance. However, it remains possible that a more exact definition of the entity “interstitial pneumonitis with autoimmune features,” currently being developed by an expert group, may have future management implications.

RELAPSING POLYCHONDritis

Relapsing polychondritis is a rare disease characterized by recurrent progressive cartilaginous inflammation. The episodic and painful inflammation results eventually in the widespread degeneration of cartilaginous structures. The diagnosis of relapsing polychondritis requires the presence of three or more of the following clinical features²⁶⁹: bilateral auricular chondritis; nonerosive, seronegative inflammatory polyarthritis; nasal chondritis; ocular inflammation; respiratory tract involvement (either upper or lower respiratory tract); cochlear with or without vestibular abnormality; and positive biopsy specimen. The presence of anticartilage antibodies may be helpful in the diagnosis.

The condition affects men and women equally and has a peak incidence between ages 40 and 60. It is considered an autoimmune process, and autoantibodies have been found directed against cartilage and type II collagen. A weak association with HLA-DR4 has been reported.²⁷⁰ Diagnosis is

chiefly clinical but can be confirmed at biopsy of affected cartilage, including tracheal rings.

Relapsing polychondritis is usually multifocal, affecting cartilage of the ear (85% to 94%), nose (54% to 57%) (Fig. 65-7A and B), upper respiratory tract (31% to 48%), and ribs. In addition, patients frequently suffer ocular inflammation, nonerosive arthropathy (52%), and vestibulocochlear dysfunction.^{269,271} Relapsing polychondritis may be associated with a wide range of other conditions, especially CTD and vasculitis. Approximately 30% of patients have a preexisting CTD.

Respiratory involvement probably accounts for around 10% of deaths in this condition. Up to 25% of cases present with focal or generalized respiratory tract involvement. The larynx and upper trachea are the most common focal areas involved, but large or small airways may also be affected. Laryngotracheal involvement is a poor prognostic determinant. Destruction and obstruction of the glottis, trachea, and bronchi may lead to airway stricture, collapse, and distal infection.²⁷² Pulmonary parenchymal disease is rare, with the exception of pulmonary vasculitis.

The site of cartilaginous involvement determines the clinical presentation. Upper airway involvement typically presents with wheezing and hoarseness. Lung function testing shows diminution in maximal inspiratory (large, extrathoracic airways) and expiratory (smaller, intrathoracic airways) flow rates, suggesting airway collapse. Static recoil pressures are preserved. Chest radiography may show ectopic airway cartilage calcification or large airway narrowing (see Fig. 65-7C) but is often insensitive. However, high-resolution CT scanning shows tracheal ring thickening, airway wall attenuation, and calcification (Fig. 65-8A, see Fig. 18-32). Postexpiratory CT scanning, using either scanning at the completion of a forced vital capacity maneuver (see Fig. 65-8B) or cine scanning during such a maneuver, shows extensive tracheobronchial collapsibility and can help to localize the large airway disease.²⁷³ Bronchoscopy may show endobronchial inflammation or stenosis and is useful in the exclusion of mechanical obstruction. Endobronchial biopsy may be diagnostic but is insensitive.

Figure 65-8 Relapsing polychondritis: chest CT appearance. **A**, Axial unenhanced chest CT shows thickening of the anterior two thirds of the trachea (arrows), with sparing of the posterior tracheal membrane; this pattern is typical of relapsing polychondritis. A small focus of calcification is present in the anterior tracheal wall at the 1 o'clock position (arrowhead). **B**, Axial postexpiratory HRCT image shows extensive tracheal collapse (arrows), consistent with tracheomalacia, and typical of relapsing polychondritis. **C**, Treatment of relapsing polychondritis with a self-expandable endoluminal metallic stent shows patency of the tracheal lumen. (Courtesy Michael Gotway, MD.)

Laryngoscopy and bronchoscopy are associated with risk of acute airway compromise, however.²⁷²

Treatment depends on disease severity. Mild cases may be controlled with nonsteroidal anti-inflammatory drugs, but troublesome relapses may require short-term high-dose corticosteroid therapy. In acute airway involvement, high-dose intravenous corticosteroid is used. In one large review of 159 reported cases, three fourths of the patients required chronic corticosteroid therapy, which in that series, decreased the frequency, duration, and severity of flare-ups but did not prevent disease progression.²⁷⁴ Steroid-resistant lesions have been treated with immunosuppressive agents such as cyclophosphamide. Despite short-term improvement with steroid and immunosuppressive therapy, relapse and disease progression are common. More recently, there have been a number of reported responses to biologic agents, including TNF- α antagonists, anti-IL-6 therapy, and rituximab, with efficacy or partial efficacy in more than half of cases.^{275,276} Currently, biologics cannot be recommended as first-line therapy but may have an important role in cases refractory to corticosteroids and as steroid-sparing agents. Tracheostomy and stenting are occasionally indicated, but other surgical treatment is difficult owing to the diffuse nature of involvement and risk of relapse.²⁷⁷ In one study, the use of multiple, self-expandable stents (see Fig. 65-8C) via fiberoptic bronchoscopy in five patients requiring mechanical ventilation resulted in improvement in four patients who were all able to live without mechanical ventilation for up to 20 months.²⁷⁸ Newer self-expanding silicone stents have been used with variable effect in palliative cases.²⁷⁹ Intraluminal stents may be complicated by hemorrhage, tracheal erosion, ulceration, or airway obstruction, however. Survival has been reported at 94% at 8 years.²⁸⁰

BEHÇET SYNDROME

Behçet syndrome is found predominantly in the countries bordering the Mediterranean Sea. Prevalence estimates

Table 65-8 Behçet Syndrome

CRITERIA FOR DIAGNOSIS
Major (required)
Recurrent aphthous ulceration at least 3 times in a 12-mo period
Minor (2 of 4)
Recurrent genital ulceration
Ocular disease
Skin lesions (erythema nodosum, skin ulcers)
Positive pathergy test (a 2-mm erythematous papule or pustule at the prick site 48 hr after the application of a sterile hypodermic 20- to 22-gauge needle that obliquely penetrated avascular antecubital skin to a depth of 5 mm)

approach 80 to 370/100,000 population in Turkey. Men and women are affected equally, and age of onset is usually in the second or third decade. There is an association between the HLA-B51 allele and, more controversially, more severely affected patients; relative risk of HLA-B51 carriers is roughly 13:1 in Turkey. Herpes simplex type 1 and streptococci have been suggested as causative agents.²⁸¹ Diagnosis requires the development of recurrent oral ulceration at least three times in a 12-month period and the presence of two of the four minor features listed in Table 65-8.²⁸² Mucocutaneous ulceration is the clinical hallmark, with aphthous oral and genital ulceration seen in almost all patients. Other cutaneous features include erythema nodosum, an acneiform rash, and papular lesions of cutaneous vasculitis. Uveitis is the major cause of morbidity, but systemic vasculitis may affect all systems.

Pulmonary involvement is seen in 1% to 7% and tends to affect HLA-B51-positive younger males (<25 years) more severely. The major pulmonary manifestations are pulmonary vasculitis,²⁸³ pulmonary artery aneurysms, arterial and venous thromboses, pulmonary infarction, organizing pneumonia, and pleurisy.²⁸⁴ Symptoms include dyspnea, chest pain, and recurrent hemoptysis that can be massive and fatal.²⁸⁵

The cardinal histologic feature is vasculitis affecting arterial and venous vessels of all sizes. Pulmonary arterial aneurysms are surrounded by inflammatory infiltrates and have thickened intima and degeneration of the elastic lamina with thrombosis. Behçet syndrome may be accompanied by arterial and venous thromboses, pulmonary infarcts, and occasionally, pleural effusion.²⁸⁶ The radiographic abnormalities are nonspecific but may include the features of small airway disease, pulmonary hemorrhage, vascular occlusion, or mass lesions representing arterial aneurysm(s) (see eFig. 67-2).^{287,288} Prognosis is variable. The disease course is relapsing remitting. Pulmonary artery aneurysm carries the worst prognosis, with a 2-year survival of 70%.

Treatment is complex and depends on presentation. Steroids and immunosuppressive agents are used to control vasculitis, particularly in cases of pulmonary artery aneurysm, in which eventual regression is sometimes observed. Cyclosporin A and FK506 have been successful in some patients.²⁸⁴ Anticoagulants may be required for control of thrombosis but should be used only if immunosuppression is insufficient because there is a significant risk of hemorrhage. However, controlled data are lacking and accumulated experience mostly relates to the treatment of systemic disease, including orogenital ulceration, and must be applied to pulmonary disease with caution. Acknowledging this caveat, the major recent change in treatment has been the increasing use of anti-TNF therapy, found to be efficacious for oral ulceration and skin lesions in a randomized controlled trial²⁸⁹ and endorsed for eye disease, neurologic disease, and gastrointestinal disease by a position paper, based on a definitive review of uncontrolled treatment data.²⁹⁰ For pulmonary artery aneurysms, pulmonary embolization and surgical resection have been reported to be successful, but surgical treatment of aneurysms can result in aneurysms at the anastomosis site.²⁹¹

ANKYLOSING SPONDYLITIS

Ankylosing spondylitis (AS) is a seronegative spondyloarthritis developing in 0.05% to 1.5% of the general population and is associated with the major histocompatibility antigen HLA-B27.²⁹² The prevalence of AS is higher in white males, with a male-to-female ratio of 10:1. The cardinal site of disease is the vertebral column. As the disease progresses, inflammation leads to fibrosis and ossification, with ankylosis of the vertebral joints. Peripheral joint arthritis is seen in approximately one third of patients, and extra-articular features include aortic regurgitation, uveitis, pulmonary disease, and extrapulmonary restriction.

Lung disease, mainly upper zone fibrosis, can be present in up to 30% of case series but fibrobullous disease is less common (see Figs. 98-16 and 98-18). In a series of 2080 patients with AS, this pattern was seen in only 1% to 2% of patients.²⁹³ Limited ILD, small airway disease, bronchiectasis, and paraseptal emphysema are frequently present even when chest radiographic appearances are normal.²⁹⁴⁻²⁹⁶ In another study, abnormalities were seen in 15 of 21 patients, comprising thickened interlobular septa (33%), bronchial wall thickening (29%), pleuropulmonary abnormalities (29%), and linear septal thickening (29%).²⁹⁷ Pulmonary

involvement, often subclinical, is an early manifestation of AS.²⁹⁸ A subclinical lymphocytic alveolitis may be evident with BAL.²⁹⁹ Histologically, lung abnormalities consist of a variable mixture of lymphocytic infiltration, fibrosis, and bullous change. On chest radiography, diffuse reticular opacities in the upper zones are usually symmetrical and are seldom extensive except in patients with severe spinal disease³⁰⁰ or a long history of AS.²⁹³ However, apical fibrosis occasionally may precede the development of extrapulmonary disease. No proven treatment exists to prevent the development of apical fibrosis; resistance to corticosteroid therapy is the rule.

Cavities may develop within distorted fibrotic apical tissue and are sometimes colonized by mycobacteria or fungi, especially *Aspergillus fumigatus* (see Fig. 98-18), which are isolated in up to 60% of AS patients with apical cavitation.³⁰¹ Life-threatening hemoptysis is an occasional complication of mycetoma formation within cavities and may be controllable by bronchial artery embolization; the resection of a mycetoma is a treatment of last resort owing to the high prevalence of postoperative bronchopleural fistula or empyema. Advanced apical fibrosis is often associated with apical pleural thickening, but pleural disease is seldom seen adjacent to normal lung parenchyma elsewhere in the thorax. There is an increased ($\leq 10\%$) prevalence of pneumothorax in AS patients with apical fibrosis,²⁹³ probably due to subpleural bullous degeneration in advancing disease.

Extrapulmonary restriction due to immobilization of the chest wall (costovertebral ankylosis) is an occasional complication of AS. Extrapulmonary restriction is often asymptomatic and associated with surprisingly little impairment in pulmonary function, perhaps because the diaphragm is able to make a major contribution in the presence of a high resting volume. Lung volumes may be mildly reduced, but gas transfer is almost always preserved in the absence of parenchymal disease.³⁰²

MARFAN SYNDROME

Marfan syndrome (MS) is an autosomal dominant condition of variable penetrance affecting approximately 5/100,000 population. MS is characterized by abnormalities of fibrous connective tissue with abundant type I collagen (in some cases due to mutations on chromosome 15), especially in the skeleton (long limbs, arachnodactyly, pectus excavatum, kyphoscoliosis), eyes (subluxation of the lens), and cardiovascular system (aortic or mitral regurgitation, aortic aneurysm). The reduced life expectancy of MS is largely attributable to cardiac complications; there is no effective treatment to reverse disease or slow progression.

Respiratory complications can be subdivided into pulmonary and extrapulmonary abnormalities. Ten percent to 15% of patients with MS have pulmonary involvement. The most common pulmonary complication is pneumothorax (often recurrent and bilateral). The high prevalence of pneumothorax in MS of 5% to 10%³⁰³ (>100-fold higher than in the general population) can be ascribed to the rupture of subpleural bullae. Localized bulla formation with a predilection for the lung apex³⁰⁴ is an occasional striking finding in young patients. Emphysema is present on

chest radiography in the majority of MS patients with pneumothoraces.^{303,305} Lung histologic appearances in MS are poorly characterized, but in a small series of patients with absent or minimal smoking histories, a pattern of distal acinar emphysema was evident in all cases.³⁰⁶ Generalized emphysema in nonsmoking patients with MS may become evident at any age and is sometimes fatal in childhood.³⁰⁷ Underlying apical fibrosis has been reported in a handful of cases. Other less frequent parenchymal manifestations include congenital malformations of the middle lobes (which may be absent or rudimentary) and an increased prevalence of bronchopneumonia.³⁰³

Thoracic cage involvement is present in greater than 50% of MS patients. Isolated pectus excavatum in MS is seldom associated with significant impairment in lung function. However, occasionally kyphoscoliosis is associated with fatal cor pulmonale.³⁰⁸ It is likely that nocturnal desaturation amplifies hypoxemia due to kyphoscoliosis. Increased upper airway collapsibility during sleep is common in MS, accounting for an association between MS and obstructive sleep apnea.³⁰⁹

Key Points

- In connective tissue diseases, the lung can be involved by a wide variety of patterns of pathology, from the trachea to the parenchyma to the pleura.
- Sometimes, pulmonary manifestations may precede the systemic features of the connective tissue diseases.
- Often, combinations of patterns exist that raise the likelihood that connective tissue disease is the underlying problem. Some patterns of lung disease are more common in one connective tissue disease than the others. Specific pathologic entities that are seen in

these diseases do not generally follow the same course as their idiopathic counterparts.

- Common drugs used in the treatment of connective tissue diseases may result in major pulmonary complications.
- Increasing recognition of the pulmonary manifestations of these protean disorders is resulting in better outcomes.

eFigure 65-1 High-resolution CT (HRCT) of mild systemic sclerosis lung disease. **A and B,** Axial prone HRCT imaging in a patient with scleroderma shows mild, faint reticulation. **C and D,** Axial prone imaging in a patient with scleroderma shows some faint reticulation, with more prominent subpleural ground-glass opacity. (Courtesy Michael Gotway, MD.)

eFigure 65-2 High-resolution CT (HRCT) of moderate systemic sclerosis lung disease. Axial supine HRCT imaging shows moderate basal, subpleural ground-glass opacity associated with reticulation. The pattern is identical to idiopathic nonspecific interstitial pneumonia. (Courtesy Michael Gotway, MD.)

eFigure 65-3 High-resolution CT (HRCT) of progressive systemic sclerosis lung disease. **A**, Axial prone HRCT image shows faint, subpleural basal ground-glass opacity. **B**, Axial prone HRCT image 1 year following **A** shows worsening of basal, subpleural ground-glass opacity and reticulation. (Courtesy Michael Gotway, MD.)

eFigure 65-4 Progressive systemic sclerosis (PSS). **A**, The interstitial fibrosis of PSS is typically paucicellular and diffuse, with preservation of underlying lung architecture. **B**, When fibrosis is more advanced, distinction from usual interstitial pneumonia (of idiopathic pulmonary fibrosis) may be difficult on morphologic grounds. **C**, Pulmonary hypertensive changes may be present and deserve careful attention because this is a major cause of mortality in scleroderma patients with lung disease. (From Leslie KO, Wick MR: Practical pulmonary pathology: a diagnostic approach: a volume in the pattern recognition series, ed 2. Philadelphia, 2011, Elsevier, Figs. 7-39 and 7-40.)

eFigure 65-5 Rheumatoid arthritis (RA) lung disease. **A,** Variable interstitial fibrosis is typical and often resembles the fibrotic form of nonspecific interstitial pneumonia. **B,** Most of the lymphoid aggregations in RA are present around the terminal airways (“follicular bronchiolitis” when lymphoid germinal centers are prominent), but lymphoid follicles may also be present in the pleura. **C,** Typical rheumatoid nodules may appear in RA lung and must be distinguished from lesions seen with infection and in granulomatosis with polyangiitis. **D,** The presence of chronic pleuritis should always raise the possibility of RA in the differential diagnosis. (From Leslie KO, Wick MR: Practical pulmonary pathology: a diagnostic approach: a volume in the pattern recognition series, ed 2. Philadelphia, 2011, Elsevier, Figs. 7-38 and 7-35.)

Figure 65-6 High-resolution CT (HRCT) of accelerated interstitial pneumonia in a patient with rheumatoid arthritis. **A**, Frontal chest radiography shows basal reticulation and linear opacities consistent with interstitial lung disease in the setting of rheumatoid arthritis. **B**, Axial supine HRCT image shows basal reticulation, patchy subpleural ground-glass opacity, and traction bronchiectasis. **C**, Frontal chest radiography performed several years following **A** and **B**, when the patient developed severe shortness of breath, shows diminished lung volumes with development of extensive bilateral opacities. **D**, Axial supine HRCT image focused on the left base shows progression of the basal lung abnormalities seen previously; similar findings were now also present in the mid and upper lungs (**E**). Surgical lung biopsy showed diffuse alveolar damage. The pneumomediastinum was postoperative in nature. (Courtesy Michael Gotway, MD.)

eFigure 65-7 High-resolution CT (HRCT) of diffuse interstitial fibrosis in systemic lupus erythematosus. A–D, Axial supine HRCT images show multifocal, bilateral, patchy areas of reticular and linear opacities, including interlobular septal thickening (*double arrowheads*), associated with ground-glass opacity (*arrowheads*) and mild architectural distortion. Mild traction bronchiectasis (*arrow*) is evident. The findings are nonspecific, but surgical lung biopsy showed features suggestive of a connective tissue disorder (enlarged peribronchiolar lymphoid follicles). (Courtesy Michael Gotway, MD.)

eFigure 65-8 High-resolution CT (HRCT) of diffuse alveolar hemorrhage in systemic lupus erythematosus. A and B, Axial supine HRCT images show multifocal bilateral ground-glass opacity, with a somewhat centrilobular nodular appearance in the upper lobes (**A**). (Courtesy Michael Gotway, MD.)

Figure 65-9 Spectrum of Sjögren-related pulmonary abnormalities. **A** and **B**, Axial supine high-resolution CT (HRCT) images show basal reticulation, mild ground-glass opacity, and traction bronchiectasis in the subpleural lower lobes, consistent with a nonspecific interstitial pneumonia pattern. **C**, Axial prone HRCT image shows coarse basal reticulation, subpleural cystic change, and traction bronchiectasis, consistent with a usual interstitial pneumonia pattern. **D**, Axial supine HRCT image shows peripheral consolidation (arrows) consistent with an organizing pneumonia pattern. **E**, Axial supine HRCT image shows several poorly defined ground-glass opacity nodules (arrows), representing lymphocytic interstitial pneumonia. This appearance is nonspecific and can be seen with other lymphoproliferative disorders that may be encountered in Sjögren patients, including follicular bronchiolitis, nodular lymphoid hyperplasia, and even MALT lymphoma. **F** and **G**, Axial supine HRCT image shows multiple, bilateral poorly defined pulmonary nodules found to represent MALT lymphoma. Note the air bronchograms associated with one of the nodules (arrowhead), indicating the bronchiolocentric nature of the process. **H** and **I**, Axial supine HRCT images show multiple thin-walled cysts and small nodules (arrow), one of which shows a small focus of calcification (arrowhead) on the images displayed in soft tissue windows (**J**). **K–N**, Axial supine HRCT images in a patient with Sjögren syndrome show multiple, bilateral, thin-walled cysts with normal intervening lung parenchyma. (Courtesy Michael Gotwax, MD.)

eFigure 65-10 Diffuse alveolar damage superimposed on pulmonary interstitial abnormalities in a patient with polymyositis-dermatomyositis. Axial prone high-resolution CT image shows patchy, subpleural reticulation and areas of consolidation, consistent with a mixture of nonspecific interstitial pneumonia and organizing pneumonia injury patterns. Patchy areas of ground-glass opacity, spatially separated from the subpleural process, represent areas of diffuse alveolar damage. (Courtesy Michael Gotway, MD.)

INTRODUCTION

Sarcoidosis has been defined as a multisystem granulomatous disorder of unknown cause.¹ Sarcoidosis affects the lung in over 90% of cases but can affect any part of the body. For many patients the disease is self-limited and resolves within 2 to 5 years.² However, a chronic form of the disease can lead to significant morbidity and some mortality.^{3,4} Glucocorticoids are usually effective for treating the disease; however, because long-term treatment may be required, steroid-sparing agents are often used.⁵

EPIDEMIOLOGY

Sarcoidosis is a worldwide disease, but it is more common in some parts of the world and within certain ethnic groups. Figure 66-1 summarizes the reported rates of sarcoidosis around the world.⁶ In the United States the disease appears to be more common in the southeastern part of the country.

Sarcoidosis is rare before adulthood.⁷ Pediatric sarcoidosis is usually diagnosed in patients older than 10 years, with a peak in the 13- to 15-year-old age group.⁸ When it does present in childhood, there is a different clinical phenotype with mostly eye (uveitis), skin, and joint involvement, although lung involvement is commonly identified when lung imaging studies are performed.⁹ The clinical appearance of juvenile-onset sarcoidosis resembles that of the adult type of the disease.^{10,11} As in adults, the most common finding in childhood sarcoidosis is a chest radiograph with abnormal findings (>90% at onset, with stage I in two thirds of the subjects).¹² Although previously felt to be a disease mostly of young adults, it has been increasingly diagnosed in older patients. In the United States, half of the patients are older than age 40.¹³ There appear to be two peaks of age of onset, 20 to 29 years and 60 to 65 years.^{7,13,14}

Sarcoidosis is believed to be more common in women compared to men at a ratio of less than 2 : 1.^{7,15}

ETIOLOGY

Although sarcoidosis was first described as a distinct clinical entity more than 140 years ago, its cause remains unknown. It is rational to expect that the immunopathogenesis of sarcoidosis is similar to that of other granulomatous diseases. That is, some antigen is encountered and phagocytized by an antigen-presenting cell. The antigen-presenting cell then processes the antigen and presents it, via a *human leukocyte antigen* (HLA) class II molecule, to a restrictive set of T-cell receptors on a T lymphocyte, usually of the CD4⁺ class.^{16,17} This interaction results in a polarization of the T lymphocytes to a type 1 T-helper phenotype, which is followed by monocyte recruitment, T-cell proliferation, and differentiation leading to the development of the sarcoidosis granuloma. In this process a myriad of cytokines and chemokines is released, but the relative importance of most of them is unclear.

POTENTIAL ANTIGENS

Because many infections induce a granulomatous response, infectious pathogens have been implicated as potential causes of sarcoidosis. However, because sarcoidosis responds to immunosuppressive therapy, it is unlikely that sarcoidosis represents an invasive infection; it is nonetheless possible that a host response to an infectious antigen, even if the infecting organism is dead, may induce a granulomatous response. For example, propionibacteria, including *Propionibacterium acnes*, the common acne bacterium, have also been implicated as a cause of sarcoidosis. Propionibacterial DNA has been detected within granulomatous lymph nodes

Figure 66-1 Prevalence of sarcoidosis around the world. (Adapted from Denning DW, Pleuvry A, Cole DC: Global burden of chronic pulmonary aspergillosis complicating sarcoidosis. *Eur Respir J* 41:621–626, 2013. doi: 10.1183/09031936.00226911, published ahead of print June 27, 2012. Reproduced with permission of the European Respiratory Society.)

of Japanese sarcoidosis patients.¹⁸ These findings have not been corroborated, however, in subsequent studies outside of Japan.¹⁹

Mycobacteria have been implicated as a potential cause of sarcoidosis. More than two dozen studies have assessed the presence of mycobacterial DNA and RNA in sarcoidosis tissues.²⁰ A meta-analysis has suggested that 26% of sarcoidosis tissues have evidence of mycobacterial DNA that is 9- to 19-fold greater than in nonsarcoidosis control tissues.²¹ However, quantitative polymerase chain reaction comparing lung tissue from sarcoidosis patients, controls, and those with tuberculosis in an area in which tuberculosis is endemic (China) found that the copies of mycobacteria DNA identified in the tissue from sarcoidosis patients were at levels similar to those of control tissues and 1000-fold less than in the tissues of patients infected with *Mycobacterium tuberculosis*.²² It is therefore not clear that mycobacterial DNA is consistently higher in the tissues of patients with sarcoidosis.

The protein mycobacterial catalase-peroxidase has been identified in human sarcoidosis tissue and has been shown to induce an immunoglobulin G antibody response in 12 of 25 sarcoidosis patients compared to purified protein derivative–negative controls.²³ Subsequent studies have demonstrated a T-lymphocyte response to mycobacterial catalase-peroxidase both in the peripheral blood and bronchoalveolar lavage (BAL) of sarcoidosis patients.^{20,24,25}

Environmental and occupational exposures may also be associated with sarcoidosis.^{26,27} Combustible wood product exposure may be associated with sarcoidosis, because the incidence and prevalence of sarcoidosis in firefighters far exceeds that of emergency medical technicians who travel to the same fires.²⁸ In addition, a relationship between wood stove/fireplace exposure and the development of sarcoidosis has been documented.²⁹ An increased incidence of a sarcoidosis-like granulomatous lung process was found in firefighters and first responders involved in the World Trade Center disaster who were exposed to large amounts of debris during a prolonged period.^{30–32} It is not clear, however, whether patients exposed to World Trade Center debris exhibit the same clinical features as patients with non–World Trade Center–related sarcoidosis.

An increased incidence of sarcoidosis has been found in individuals exposed to metals, in particular, titanium,³³ metalworking, metal machining,³³ and photocopier toner (that contains silicates, iron, and copper).³⁴ Analysis of lung biopsy specimens from pulmonary sarcoidosis patients has revealed various metals, including silicates, aluminum, and titanium.³⁵ Sarcoidosis has also been associated with several additional occupations and exposures, including hairdressers,³⁶ health care workers,³⁷ agricultural employment,²⁷ insecticide use at work,²⁷ work environments with mold or mildew,²⁷ industrial organic dust exposure, educators, and workers of suppliers of building materials, hardware, and gardening materials.²⁶ Many of these exposures may, in and of themselves, cause granulomas. Many of the sarcoidosis cases associated with environmental exposure to respirable material are of isolated pulmonary sarcoidosis.³⁸ It is not clear whether these are truly cases of sarcoidosis or of “sarcoid-like” conditions (e.g., hypersensitivity pneumonitis).

GENETIC ASPECTS

There is compelling evidence that sarcoidosis is the result of environmental triggers acting upon an immunogenetically susceptible host.³⁹ The importance of genetics in the development of sarcoidosis is further supported by evidence of familial clustering of the disease.^{40–42}

Because HLA class II molecules and T-cell receptors appear integral to the immunopathogenesis of sarcoidosis,¹⁷ various polymorphisms of these molecules have been examined for their association with sarcoidosis. Indeed, some HLA polymorphisms have been found to be associated with sarcoidosis.⁴³ Most of these associations appear in specific ethnic groups and have not been universal.⁴⁴ In addition, some HLA polymorphisms appear to protect against sarcoidosis,⁴⁴ whereas others are associated with certain clinical phenotypes.^{45–48} The presence of *HLA-DRB1*03* in a Swedish sarcoidosis cohort was strongly associated with a Löfgren syndrome phenotype and also with disease resolution.^{49,50} Thus the presence or absence of *HLA-DRB1*03* could provide clinical prognostic information in the near future.

Although not studied as extensively as HLA molecules, specific arrangements of T-cell receptors have also been associated with sarcoidosis. A restricted use of T-cell receptor α and β chain variable gene segments on T cells in the lungs of sarcoidosis patients has been identified.⁵¹

Non-HLA class II genes have also been shown to be associated with sarcoidosis. HLA class I polymorphisms have been associated with sarcoidosis susceptibility.⁵¹ In a study of German families the *butyrophilin-like 2* (*BTNL2*) immunoregulatory gene explained 23% of the sarcoidosis risk in that population.⁵² Other genome-wide approaches have implicated regions associated with sarcoidosis in chromosome 5 in an African American population⁵³ and mutations in the annexin 1 gene in a German population.⁵⁴ Gene-wide assays have been used to identify other potential associations.⁵⁵ Bioinformatic analyses of global gene expression (“pathway analysis”) identified a dominant network regulated by signal transducer and activator of transcription-1 as the most significantly associated with sarcoidosis in a study of lung and lymph nodes⁵⁶ and identified genes associated with type 1 T-helper cells, type 17 T-helper cells, signal transducer and activator of transcription-3, and interleukin-21 in sarcoidosis skin tissue.⁵⁷

SARCOIDOSIS AS THE RESULT OF IMMUNE SYSTEM EXHAUSTION

Chen and colleagues⁵⁸ demonstrated intense expression and wide distribution of serum amyloid A within the sarcoidosis granuloma that surpassed that found in all other granulomatous diseases examined. Serum amyloid A appeared to have originated from macrophages and giant cells within the sarcoid granuloma. These authors postulated that serum amyloid A could bind to matrix proteins and thereby consolidate a poorly soluble protein aggregate to form a nidus for granuloma formation. Serum amyloid A may disrupt the clearance of an antigen within the granuloma that allows for its persistence. Therefore sarcoidosis may relate not only to certain exposures or antigens but also to failure of effective antigen clearance. The granulomatous inflammation in sarcoidosis may result from a prolonged immunogenic response to a persistent antigen resulting in “immune system exhaustion.”⁵⁹

Evidence for a potential role of immune system exhaustion from chronic stimulation as an integral mechanism in the formation of the sarcoid granuloma is beginning to emerge. Invariant natural killer T cells have been found to be depleted in sarcoidosis, and this is postulated to be the result of functional exhaustion.⁵⁹ *T regulatory* (Treg) cells have been found to be increased in the BAL of several granulomatous diseases,^{60,61} including sarcoidosis.^{61,62} Increased Treg cells in the BAL of sarcoidosis is associated with more active disease.^{61,62} Treg cells may induce anergy and mollify the immune response. However, recent data suggest that there is an anergic response in CD4 T cells in sarcoidosis that is not reversed by Treg cell depletion.⁶³ This suggests that CD4 T-cell exhaustion may be a primary event in sarcoidosis.

DIAGNOSTIC APPROACH

Histologic evidence of granulomatous inflammation *alone* is inadequate for the diagnosis of sarcoidosis because alternative causes of granulomatous inflammation need to be excluded. Additionally, with rare exceptions (see later), clinical findings without histologic confirmation of granuloma-

tous inflammation are inadequate to secure the diagnosis of sarcoidosis.

Figure 66-2 outlines the approach to the diagnosis of sarcoidosis. This process usually involves a review of clinical information, histologic examination of tissue for the presence of granulomatous inflammation, and exclusion of known causes of granulomatous inflammation.⁶⁴

CLINICAL DATA COLLECTION

One can never be certain of the diagnosis of sarcoidosis. Similar to other diseases, sarcoidosis may be considered as the probable diagnosis if clinical data exceed a certain “threshold” so that the diagnosis is plausible. Table 66-1 outlines clinical findings that are often used to gauge the likelihood of the diagnosis of sarcoidosis. For most patients the clinical information suggests the diagnosis, but a tissue biopsy is usually indicated to enhance the probability of sarcoidosis.

Patients with sarcoidosis may present with no symptoms. This is more common in white than black patients.⁶⁵ Therefore sarcoidosis should be considered in asymptomatic patients with hilar adenopathy, mediastinal adenopathy, and/or diffuse parenchymal opacities on lung imaging.⁶⁵⁻⁶⁷ An inquiry should be made about a family history of sarcoidosis because the prevalence rate of sarcoidosis is much higher in first-degree relatives of sarcoidosis patients than in the general population.⁴¹ Sarcoidosis is more common in nonsmokers than in smokers in most studies.^{27,68,69}

In addition, patients should be questioned concerning potential exposures that may cause diseases that may mimic sarcoidosis. Specifically, a history of active tuberculosis, latent tuberculosis infection, and tuberculosis exposure should be obtained. The possibility of beryllium exposure should be explored because chronic beryllium disease can mimic sarcoidosis radiographically⁷⁰ and histologically.^{71,72} Chronic beryllium disease has been misdiagnosed as sarcoidosis in up to 40% of cases.⁷³ Because most patients are unaware of potential exposures to beryllium, it is important to ask about work industries where exposure to beryllium is plausible, including aerospace, nuclear weapons, electronics, jewelry, sporting goods, ceramics, and dental.⁷⁴ Furthermore, minimal beryllium exposure may lead to significant disease.^{75,76} Hypersensitivity pneumonitis, which may mimic sarcoidosis, is a granulomatous pulmonary disease resulting from exposure to numerous agents (see Chapter 64).

EVIDENCE OF EXTRAPULMONARY INVOLVEMENT

At presentation, 95% of sarcoidosis patients have clinical evidence of pulmonary involvement, and more than 40% have evidence of involvement in the skin, liver, peripheral lymph node, or eye.¹³ Therefore evaluation for involvement of these organs should be performed in any patient being evaluated for possible sarcoidosis.

RADIOGRAPHIC FINDINGS

Bilateral hilar adenopathy on chest radiograph suggests the diagnosis of sarcoidosis, especially if the patient has no

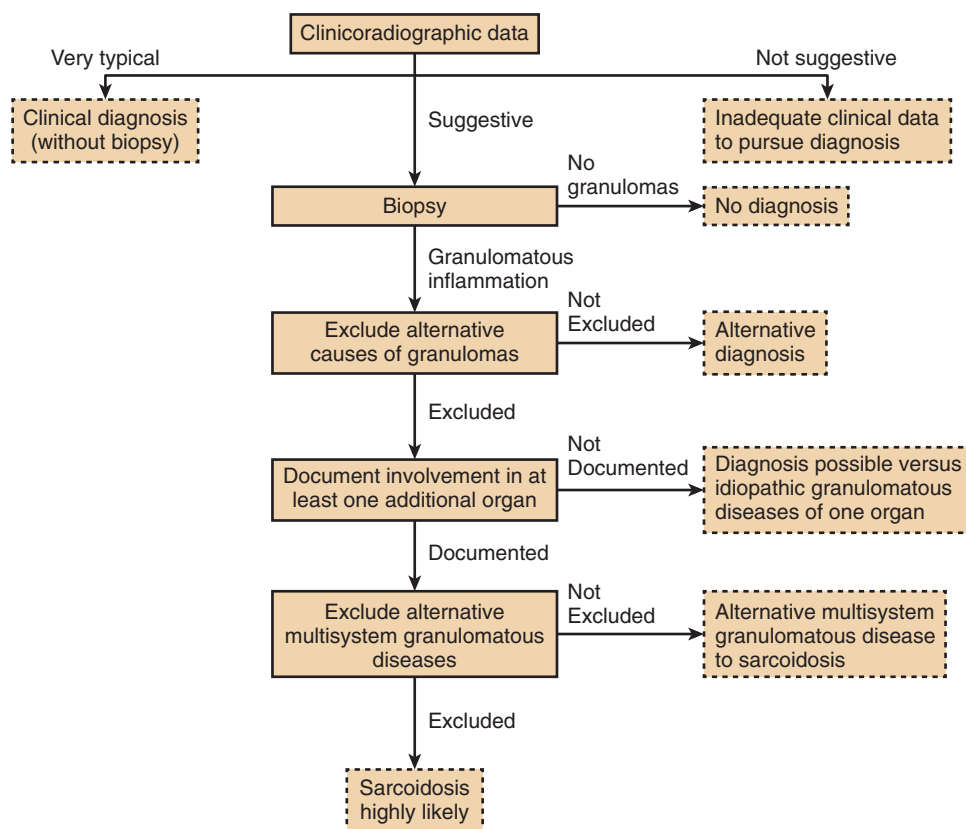

Figure 66-2 Diagnostic algorithm for sarcoidosis. The figure outlines the diagnostic approach for sarcoidosis with consideration of clinical information and tissue biopsy demonstration of granulomatous inflammation as well as exclusion of known causes of granulomatous inflammation (see text for details). (Adapted from Judson MA: The diagnosis of sarcoidosis. *Clin Chest Med* 29:415–427, 2008.)

Table 66-1 Clinical and Chest Imaging Data Supporting or Weakening the Likelihood of Sarcoidosis

	Supports	Weakens

fever, night sweats, or weight loss.^{66,67} The chest radiograph often demonstrates concomitant enlargement of the right paratracheal lymph nodes⁷⁷ (Fig. 66-3). Scadding⁷⁸ defined four patterns of the chest radiograph findings: stage 1, with adenopathy alone (see Fig. 66-3); stage 2, adenopathy and parenchymal opacities (Fig. 66-4); stage 3, opacities alone (Fig. 66-5); and stage 4, fibrosis (Fig. 66-6).

Findings on chest *high-resolution computed tomography* (HRCT) may be more specific for the diagnosis of sarcoidosis than those found on chest radiography (see Figs. 66-3 to

66-6). Typical HRCT findings that suggest sarcoidosis include parenchymal nodules and opacities that represent conglomerations of these nodules that have a perilymphatic distribution along the bronchovascular bundles as well as in subpleural locations.⁷⁹⁻⁸¹

SERUM MARKERS FOR DISEASE

Angiotensin-converting enzyme (ACE) is produced in the epithelioid cell of the sarcoid granuloma, and *serum ACE*

Figure 66-3 Sarcoidosis: Scadding stage 1. **A**, Frontal chest radiograph shows symmetric, bilateral peribronchial (arrows) and right paratracheal lymphadenopathy (arrowhead), typical of sarcoidosis. **B** and **C**, Contrast-enhanced chest CT confirms the presence of symmetric, bilateral peribronchial (arrows) and right paratracheal (arrowhead) lymphadenopathy, as well as enlargement of other mediastinal lymph nodes (*). (Courtesy Michael Gotway, MD.)

Figure 66-4 Sarcoidosis: Scadding stage 2. **A**, Frontal chest radiograph shows symmetric, bilateral peribronchial lymph node enlargement (arrows) as well as small, well-defined nodules best visualized in the right suprahilar region. The oblong opacity in this area represents a conglomeration of granulomatous inflammation. **B-D**, Axial enhanced chest CT displayed in lung (**B** and **C**) and soft tissue (**D**) shows small, circumscribed nodules distributed along the fissural surfaces (white arrowheads, **B** and **C**) and soft tissue (black arrowheads, **C**), the latter resulting in a “beaded” appearance of the pulmonary vessels. Chest CT also confirms the presence of peribronchial lymph node enlargement (arrows, **D**). (Courtesy Michael Gotway, MD.)

(SACE) levels may reflect the total body burden of sarcoidosis granulomas.⁸² Although SACE has been suggested as a diagnostic test for sarcoidosis,⁸³ elevated SACE levels alone are inadequately sensitive or specific to diagnose or exclude the disease. In a review of 14 studies encompassing 4195 patients concerning the diagnostic accuracy of SACE for sarcoidosis, the sensitivity was 77% (range, 41% to 100%) and the specificity was 93% (range, 83% to 99%).⁸⁴ The likelihood of sarcoidosis increases with higher SACE levels,^{84,85} and SACE levels greater than two times the upper limit of normal are rarely seen in other diseases and not seen in cancer or lymphoma.^{83,86} Polymorphisms of the *ACE* gene also influence the SACE level and likely alter the

diagnostic accuracy of SACE measurements in individual patients.⁸⁷ In addition, none of these polymorphisms have been shown to be associated with increased incidence or worsening of the disease.⁸⁸ Furthermore, the differences of these polymorphisms between the white and African American populations suggest that the role of the polymorphism of the *ACE* gene is population dependent, and this explains the reported racial difference in the relationship between SACE levels and the polymorphism.

Other serum markers have been studied in sarcoidosis. These include serum chitotriosidase, which has been shown to be elevated in a small cohort of Italian sarcoidosis patients. Higher serum levels may be associated with a

Figure 66-5 Sarcoidosis: Scadding stage 3. **A**, Frontal chest radiograph shows upper lobe–predominant nodular opacities with little evidence of architectural distortion to suggest associated parenchymal fibrosis. No clear evidence of peribronchial or mediastinal lymph node enlargement is present. Mild prominence of the left hilum is due to parenchymal opacity projected over this region, as shown at chest CT. **B** and **C**, Axial chest CT displayed in lung windows shows small, circumscribed nodules distributed along the fissural surfaces (*arrowheads*), as well as along the more central peribronchovascular interstitium (*arrows*), the latter resulting in a “beaded” appearance of the pulmonary vessels. Additional chest CT images also confirmed the lack of significant peribronchial and mediastinal lymph node enlargement. (Courtesy Michael Gotway, MD.)

worse prognosis.^{89,90} The soluble interleukin-2 receptor is a marker of T-cell activation and found to be elevated in sarcoidosis patients.^{90,91} In small studies it was an effective measure of disease activity.^{79,91} The value of these biomarkers regarding diagnosis and prognosis needs to be verified by larger multinational trials.

TISSUE EXAMINATION

With the exception of the rare instances in which the clinical findings are highly specific for sarcoidosis, the diagnosis requires a tissue biopsy (see Fig. 66-2). Our approach to the selection of a biopsy site is summarized in Figure 66-7. It is in the patient's best interest that the biopsy be minimally invasive and associated with the least morbidity. For these reasons, superficial biopsy sites are preferred compared to visceral organs.⁹² Even in patients suspected to have sarcoidosis on the basis of obvious thoracic or abdominal disease, a thorough skin, conjunctival, lacrimal gland, and peripheral lymph node examination should be performed. The patient should be questioned about the presence of scars or tattoos (see Fig. 66-14D), because sarcoidosis skin nodules have a predilection to form in these areas.

When there is no clinical evidence that a superficial site is involved with sarcoidosis, a biopsy is usually attempted in an organ in which sarcoidosis involvement is suspected. This is very often the lung, because the lung is involved in more than 90% of sarcoidosis patients early in the course of the disease.^{13,93} Bronchoscopy is the most commonly used procedure to obtain tissue from the lung. More invasive techniques such as mediastinoscopy are reserved for cases in which bronchoscopy was not diagnostic. Video-assisted thoracoscopic biopsy is rarely needed to confirm the diagnosis of sarcoidosis.

Bronchoscopy

The bronchoscope allows for several different samples, including the *transbronchial biopsy* (TBB), endobronchial biopsy, and *transbronchial needle aspiration* (TBNA). The yield of TBB for the diagnosis of pulmonary sarcoidosis ranges from 60% to 97% depending on the number of biopsy specimens taken and the presence of parenchymal disease on chest imaging studies.⁹⁴⁻⁹⁶ Endobronchial biopsy results may be positive in up to 60% of patients with pulmonary sarcoidosis.^{97,98} Biopsy results are more frequently positive in individuals with abnormal-appearing airways but may provide the diagnosis even from normal-appearing airways.⁹⁷ Furthermore, endobronchial biopsy can be performed with TBB and increases the yield for sarcoidosis above that using TBB alone.

TBNA has been extensively evaluated as a diagnostic approach for pulmonary sarcoidosis over the last decade. The diagnostic yield is in the range of 80%.⁹⁹ The use of endobronchial ultrasonography has been shown to be superior to blind TBNA in two randomized trials.^{100,101} The yield for TBNA is much higher for patients with adenopathy on chest radiograph (stage 1 or 2), whereas the yield for TBB is higher for those with a stage 3 pattern on the chest radiograph.^{101,102} The use of on-site cytopathologic examination allows for rapid review of the TBNA specimen, and, if the TBNA is diagnostic, the bronchoscopist may not need to proceed to TBB.¹⁰³

Bronchoalveolar Lavage

Examination of inflammatory cells from BAL fluid is sometimes used as a complementary test for the diagnosis of pulmonary sarcoidosis.¹⁰⁴ The diagnostic accuracy of the percentage of lymphocytes and the ratio of CD4/CD8

Figure 66-6 Sarcoidosis: Scadding stage 4 (findings in two patients). **A**, Frontal chest radiograph shows upper lobe linear and reticular opacities associated with architectural distortion consistent with a fibrosing process; note bilateral superior hilar retraction. There is little pleural abnormality, typical of granulomatous inflammation due to sarcoidosis as opposed to granulomatous infections. **B** and **C**, Axial chest CT displayed in lung windows shows patchy, upper lobe linear opacities associated with architectural distortion and traction bronchiectasis (*arrows*). Subpleural and perifissural nodular opacities (*arrowheads*) are present. **D**, Frontal chest radiograph in a patient with advanced lung parenchymal fibrosis related to sarcoidosis shows extensive upper lobe linear and reticular opacities associated with architectural distortion, again without significant pleural abnormality. Nodular interstitial thickening is also evident. **E** and **F**, Axial chest CT displayed in lung windows shows extensive biapical traction bronchiectasis with peribronchovascular interstitial thickening (*arrow*, **F**) and perifissural nodularity (*arrowheads*). (Courtesy Michael Gotway, MD.)

lymphocyte subpopulations in BAL has been assessed. In general, BAL lymphocytosis (>15% lymphocytes) has a 90% sensitivity for the diagnosis of sarcoidosis,¹⁰⁴⁻¹⁰⁶ although the specificity is lower. Other conditions leading to a BAL lymphocytosis must be excluded, including infections such as tuberculosis and fungal infections, lymphoma, and hypersensitivity pneumonitis.^{106,107} A BAL lymphocytosis of more than 60% and presence of mast cells is more common in hypersensitivity pneumonitis than in sarcoidosis.¹⁰⁵ The BAL CD4/CD8 ratio is increased more than 3.5 times in 50% to 60% of pulmonary sarcoidosis patients. However, the specificity of the BAL CD4/CD8 ratio criterion has approached 95% in some¹⁰⁶⁻¹⁰⁸ but not all¹⁰⁹ studies. Some have advocated that the BAL CD4/CD8 criterion is diagnostic of sarcoidosis when there are concomitant chest imaging findings compatible with sarcoidosis¹⁰⁴; however, these criteria have not been formally tested. Like other

studies, BAL provides supportive evidence for the diagnosis of sarcoidosis. In addition, BAL samples can be tested along with bronchial washings for evidence of fungal or mycobacterial infection.¹¹⁰

Extrapulmonary Tissue Biopsy

Granulomas can be detected histologically in any organ that is involved with sarcoidosis.⁹² The biopsy of neural tissue and the heart are particularly problematic because of the potential morbidity associated with these procedures. Because patients with neurosarcoidosis will have extraneural sarcoidosis nearly 90% of the time,¹¹¹ most patients have extraneural disease from which a biopsy specimen can be obtained. Although endomyocardial biopsy is a fairly specific test for cardiac sarcoidosis in the proper clinical setting, its sensitivity is very low.¹¹² For this reason, endomyocardial biopsy is rarely performed for the diagnosis of sarcoidosis.

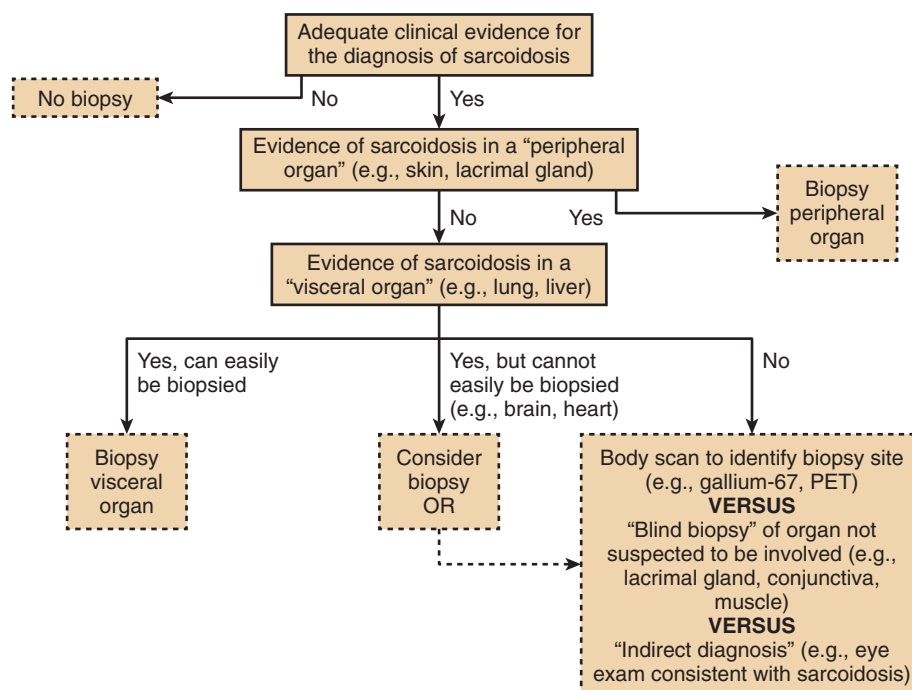

Figure 66-7 Diagnostic approach to selecting a biopsy site for pathologic confirmation of granulomatous inflammation consistent with sarcoidosis. This approach emphasizes (1) selection of a relatively noninvasive biopsy site when possible; (2) biopsy of a site suspected to be clinically involved unless the biopsy would be highly invasive; (3) consideration of alternate approaches when no obvious organ involvement is demonstrated or the only organs with potential involvement would require very invasive biopsies.

Table 66-2 Clinical Presentations That May Be Assumed to Be Sarcoidosis without Tissue Confirmation Provided Additional Data Does Not Suggest an Alternative Diagnosis

- Lupus pernio
- Löfgren syndrome⁴⁹
 - Bilateral hilar adenopathy on chest radiograph
 - Erythema nodosum skin lesions
 - Periarticular inflammation or arthritis of the ankles with or without erythema nodosum
- Heerfordt syndrome¹¹³ (parotitis, uveitis, facial palsy and fever)
 - Uveitis
 - Parotitis
 - Fever (often)
- Bilateral hilar adenopathy on chest radiograph without symptoms
- Positive panda sign (parotid and lacrimal gland uptake) and lambda sign (bilateral hilar and right paratracheal lymph node uptake) on gallium-67 scan¹¹⁶

Adapted from Judson MA: The diagnosis of sarcoidosis. *Clin Chest Med* 29:415–427, 2008.

Figure 66-8 Erythema nodosum. Tender red nodules or lumps, usually seen on both shins, are caused by inflammation of the fat cells under the skin.

Often, imaging studies are used as surrogate tests for the diagnosis of neurosarcoidosis and cardiac sarcoidosis. Such studies should be interpreted cautiously because their specificity depends upon associated clinical evidence for sarcoidosis, which should almost always include previous biopsy confirmation of granulomatous inflammation of unknown cause in another organ (see later). Also, the specificity of imaging studies for neurosarcoidosis and cardiac sarcoidosis is unknown.

Clinical Phenotypes Suggestive of Sarcoidosis

In some cases the clinical presentation of sarcoidosis is so specific that the diagnosis can be made without performing a confirmatory tissue biopsy. These presentations are listed in Table 66-2.⁶⁴ In patients with these presentations, one

may consider performing a bronchoscopy to rule out other possible causes, including infection. In patients in whom a bronchoscopy is not diagnostic, the presence of factors in Table 66-2 may help bolster confidence for the diagnosis of sarcoidosis. Lupus pernio (see Fig. 66-14A) is an indurated, raised skin lesion that is characteristically found on the ears, cheeks, and nose (see later); it is considered highly specific for sarcoidosis. Löfgren syndrome initially included only patients with erythema nodosum of lower legs or forearms (Fig. 66-8). However, periarticular inflammation or arthritis of the ankles with or without erythema nodosum has been added to the expanded definition of Löfgren syndrome.⁴⁹ Uveoparotid fever, also known as Heerfordt syndrome is unusual but specific for the diagnosis of sarcoidosis.¹¹³

Figure 66-9 Positron emission tomography (PET) scan demonstrating both lung parenchymal and mediastinal nodal uptake. Also demonstrated are several extrapulmonary lymph nodes and other areas with increased activity.

Other Diagnostic Approaches

On some occasions the diagnosis of sarcoidosis is suspected on clinical grounds although no specific organ can be found to biopsy. This would include patients presenting with disease of the eye, brain, or heart that is consistent with sarcoidosis but does not provide a safe site for biopsy. There is no established approach for this situation. Total body imaging such as ^{18}F -fluorodeoxyglucose positron emission tomography (PET)^{114,115} or gallium-67 scanning¹¹⁶ has been proposed in such cases to identify an organ for biopsy (Fig. 66-9), although no rigorous analysis of this approach has been undertaken. Another suggested approach in this situation is to biopsy organs that are commonly affected, even in the absence of symptoms or other clinical findings suggestive of sarcoidosis involvement of that organ. Conjunctival biopsies have been performed in this situation, and the yield has ranged from 27% to 55% in patients without ocular symptoms.¹¹⁷⁻¹¹⁹ In vivo confocal microscopy of the conjunctiva can detect multinucleated giant cells without the need for a biopsy, a noninvasive approach that has been advocated to confirm granulomatous inflammation in sarcoidosis patients.¹²⁰ Liver biopsy demonstrates granulomas in 24% to 78% of sarcoidosis patients, even when they have no symptoms attributable to the liver and have normal serum liver function test results.^{121,122} However, hepatic granulomas are not specific for sarcoidosis so that clinical evidence of extrahepatic sarcoidosis must be present for the diagnosis to be secure.¹²³ Andonopoulos and colleagues¹²⁴ found that gastrocnemius muscle biopsy revealed granulo-

mas in 22 consecutive patients without muscle symptoms who had bilateral hilar adenopathy on chest radiograph. However, most of these patients had strong clinical evidence of sarcoidosis; furthermore, this procedure is fairly invasive.

Another test to consider when sarcoidosis is suspected on clinical grounds although no specific organ is identified to biopsy is the Kveim-Siltzbach test. This test is only available in selected centers and may be indicated when chest imaging studies are normal (e.g., in cases of uveitis of unknown origin, hypercalciuria, hepatic granulomatous disease, suspected neurosarcoidosis, or recurrent erythema nodosum).¹ This test involves the intradermal inoculation of a suspension of splenic tissue from spleen that was involved with sarcoidosis.¹²⁵ If a skin nodule develops at the inoculation site in 4 to 6 weeks, it is biopsied. A biopsy demonstrating noncaseating granulomatous inflammation is highly specific for the diagnosis of sarcoidosis.¹²⁶ The Kveim-Siltzbach test has a false-negative rate of 20% to 40%. The sensitivity and specificity of the test vary depending on the spleen that is used to prepare the Kveim-Siltzbach reagent and the duration of disease. Transmission of infective agents is possible if the antigen is poorly prepared or controlled.¹

PATHOLOGIC FINDINGS

Granulomatous inflammation is necessary to establish a diagnosis of sarcoidosis in most cases; however, the finding of granulomas is not sufficient for the diagnosis of sarcoidosis (Fig. 66-10).^{1,64} Meticulous histologic examination with appropriate staining of all biopsy specimens should be performed to search for known causes of granulomatous inflammation, such as mycobacteria, fungi, parasites, and foreign material (e.g., talc).

Although there are no specific histologic features that are diagnostic of sarcoid granulomas, there are certain features that suggest this diagnosis. The sarcoid granuloma usually consists of a compact (organized) collection of mononuclear phagocytes (macrophages and epithelioid cells).¹²⁷ Typically there is no necrosis within the sarcoid granuloma; however, on occasion, there is a small to moderate amount of necrosis. Usually, giant cells fuse within the sarcoid granuloma to form multinucleated giant cells. These granulomas are typically surrounded by lymphocytes in the periphery. A variety of inclusions may be present within the sarcoid granuloma, including asteroid bodies, Schaumann bodies, birefringent crystals, and Hamazaki-Wesenberg bodies; however, these inclusions are neither specific nor diagnostic for sarcoidosis (Fig. 66-11).¹²⁷ In particular, birefringent crystals within the sarcoid granuloma may lead to a misdiagnosis of talc granulomatosis.⁷² Care must be taken to ensure that the crystal morphologic features and size are compatible with intravenously injected talc to ensure the diagnosis of talc granulomatosis.

Sarcoidosis has been defined as a multisystem granulomatous disorder of unknown cause.¹ The fact that the disease is “multisystem” implies that there should be evidence of granulomatous inflammation in at least two organs for the diagnosis of sarcoidosis to be secure. However, the biopsy of a second organ is not routinely performed. Of note, there are some conditions that appear to be distinct

Figure 66-10 Sarcoidosis. **A**, The characteristic pathologic lesion of pulmonary sarcoidosis is the non-necrotizing (immune) granuloma. **B**, Granuloma within sclerotic fibrosis. **C**, Granulomas distributed along lymphatic routes in the pleura, within the intralobular septa, and along the bronchovascular bundles. This image is diagnostic of sarcoidosis, but berylliosis should always be included as a diagnostic possibility. **D**, Perivascular granulomas embedded in sclerosis are commonly seen. Despite this potential for vasocentric growth, pulmonary hypertension is an uncommon complication of sarcoidosis. (Adapted from Leslie KO, Wick MR: *Practical pulmonary pathology: a diagnostic approach*, ed 2, Philadelphia, 2011, Elsevier, Figs. 7-75 and 7-78.)

Figure 66-11 Sarcoidosis. Multinucleate giant cells characteristically are present, often accompanied by a variety of distinctive (but not specific) cytoplasmic inclusions. **A**, Asteroid body. **B**, Schaumann body. **C**, Schaumann (conchoidal) bodies. **D**, Schaumann body in polarized light. (Adapted from Leslie KO, Wick MR: *Practical pulmonary pathology: a diagnostic approach*, ed 2, Philadelphia, 2011, Elsevier, Fig. 7-79.)

from sarcoidosis in which granulomatous disease seems to be limited to a single organ (e.g., idiopathic granulomatous hepatitis,^{128,129} and idiopathic panuveitis¹³⁰).

OTHER IDIOPATHIC MULTIORGAN GRANULOMATOUS DISEASES

There are other multiorgan granulomatous syndromes that should be considered in the differential diagnosis of sarcoidosis. These include infections, such as tuberculosis.

Blau syndrome consists of granulomatous iritis, arthritis, and skin rash.^{131,132} The disease is a genetic disorder¹³³ and has an autosomal dominant pattern of inheritance with variable penetrance.^{131,132} In contrast to sarcoidosis, most cases present before 12 years of age. Blau syndrome is considered a separate entity from childhood sarcoidosis on the basis of a lack of visceral (e.g., pulmonary) involvement, mode of inheritance, and absence of Kveim-Siltzbach skin test reactivity.^{131,134} Also, the Blau gene has not been found in sarcoidosis patients.¹³⁵

The *granulomatous lesions of unknown significance* (GLUS) syndrome consists of granulomatous inflammation in the liver, spleen, bone marrow, and lymph nodes, a benign course, and a tendency for recurrence. The GLUS syndrome is thought to be distinct from sarcoidosis because (1) elevated SACE levels are not found, (2) hypercalcemia is not found, (3) the Kveim-Siltzbach test results are negative, and (4) immunotyping of the T lymphocytes in the GLUS syndrome granulomas is different from that in sarcoidosis granulomas.^{136,137}

Necrotizing sarcoid granulomatosis is a systemic granulomatous vasculitis.^{138,139} Because of vascular involvement, necrosis is a prominent feature, unlike in most cases of sarcoidosis. Although the lung is commonly involved, extrapulmonary involvement is also common.¹⁴⁰ It is debated whether necrotizing sarcoid granulomatosis is a distinct clinical entity or a form of systemic sarcoidosis.¹⁴⁰⁻¹⁴²

EVALUATION OF PULMONARY DISEASE

The evaluation of pulmonary disease in sarcoidosis patients relies on three major determinants: pulmonary function, chest imaging, and symptoms. There have been several instruments developed in all three of these areas. The pulmonologist uses pulmonary function testing and chest imaging as a method to measure lung involvement. However, the patients' major concerns are how they feel and how their lung disease affects their quality of life. Dyspnea and cough are the major reasons for treatment of pulmonary sarcoidosis.

PULMONARY FUNCTION

A significant proportion of sarcoidosis patients will have normal spirometry findings and lung volumes at the time of diagnosis.^{13,93} Over time, some of these patients will develop a restrictive pattern, with reduction of lung volumes.^{3,143}

However, a significant proportion of sarcoidosis patients have obstructive lung disease.¹⁴⁴ The *diffusing capacity for carbon monoxide* (DL_{CO}) is a more sensitive measure of early interstitial lung disease¹⁴⁵ and often predicts a reduction in exercise capacity.^{145,146} A disproportionately reduced DL_{CO} (compared to lung volumes) may also be an indicator of sarcoidosis-associated pulmonary hypertension.^{147,148}

Clinical pulmonary exercise testing may be useful in assessing dyspnea in sarcoidosis patients.¹⁴⁵ Patients with normal lung function test results may still have abnormalities in exercise testing.¹⁴⁹ However, exercise testing is not well standardized and relatively cumbersome to perform. The *6-minute walk distance* (6MWD) test has been widely used to assess exercise capacity.¹⁵⁰ In sarcoidosis a reduction in 6MWD has been found to correlate with reduced *forced vital capacity* (FVC), fatigue, and quality-of-life measures.¹⁴⁶ A reduced 6MWD and oxygen desaturation have been found in patients with sarcoidosis-associated pulmonary hypertension.^{151,152} However, several factors besides cardiopulmonary function influence the 6MWD test, including muscle strength, joint disease, and neurologic symptoms.^{150,153}

LUNG IMAGING

Chest Radiograph

The findings on the routine chest radiograph have been classified into several stages, originally proposed by Scadding (see earlier).⁷⁸ The Scadding chest radiographic stages correlate with prognosis. Those with stage 1 (see Fig. 66-3) have a more than 80% chance of resolution of hilar adenopathy 2 to 5 years after presentation, whereas those with stage 3 have less than a 30% chance of resolving to a normal chest radiograph. Fibrotic changes (stage 4) do not resolve. The limitation of chest radiographic staging is that it does not characterize extrapulmonary manifestations of sarcoidosis. In addition, there is significant variability in the classification of radiographic stages even among experienced radiologists.¹⁵⁴

An alternative to monitoring the chest radiograph by Scadding staging is to compare chest radiographs serially over time. This is what is commonly done in clinical practice. The change in the chest radiograph has been shown to have good reproducibility and correlates with changes in pulmonary function.^{155,156} In one study the kappa coefficient for comparison reading was much better than for the Scadding scoring system.¹⁵⁴

Another method for scoring the chest radiograph developed by Muers and coworkers¹⁵⁷ is similar to a scoring system used for pneumoconiosis. It was shown that the portion of this score that assessed reticulation was able to detect changes after corticosteroid therapy¹⁵⁸ and after treatment with infliximab.¹⁵⁹ The scoring system was reproducible with a good kappa coefficient.¹⁵⁴ However, the scoring is tedious and does not appear practical for routine clinical practice.

Chest Computed Tomography Scanning

As noted earlier, chest *computed tomography* (CT) imaging, including HRCT, has proved useful in the diagnosis of sarcoidosis (see Figs. 66-3 to 66-6).¹⁶⁰ A scoring system for CT

Figure 66-12 Aspergilloma in sarcoid. High-resolution CT demonstrating upper lobe fibrosis with presence of an aspergilloma in the right upper lobe (arrow).

scans in sarcoidosis has been described⁷⁹ and has been suggested to assess severity of disease.¹⁶¹ However, it is unclear what features of the CT scan are important for the management of the disease. Some HRCT scan features do correlate with physiologic impairment in sarcoidosis; for example, honeycombing is associated with a reduced DL_{CO} and an increased alveolar-arterial PO_2 difference,^{162,163} and peribronchial thickening may lead to airway obstruction and air trapping.^{164,165} HRCT is also useful in defining the extent of bronchiectasis and the presence of complications, such as aspergilloma (Fig. 66-12).¹⁶⁶

Radionuclide Scanning

Radionuclide scanning has been used as an aid in the diagnosis of sarcoidosis and the assessment of organ involvement.¹¹⁵ Early studies focused on the gallium scan as a method of identifying inflammation.^{167,168} The presence of extrapulmonary disease was often useful in identifying potential areas to biopsy. In addition, uptake in the parotid and lacrimal glands ("panda sign") and/or right paratracheal and bilateral hilar areas ("lambda sign") were highly supportive of the diagnosis of sarcoidosis.¹¹⁶ Octreotide scanning has also been used as a marker of lung inflammation in sarcoidosis.¹⁶⁹

The detection of radioactive glucose uptake by PET scan has been widely applied to malignant conditions, including lung cancer and lymphoma. PET scan activity can also be quite enhanced in sarcoidosis, demonstrating diffuse activity in the lungs, mediastinal lymph nodes, and other parts of the body (see Fig. 66-9).^{114,115} The PET scan has proved useful in identifying potential areas for biopsy in those suspected of sarcoidosis.¹¹⁴ It has also been found to demonstrate ongoing activity in patients who are receiving immunosuppressive therapy and may suggest that the disease will relapse when therapy is withdrawn.^{170,171} Patients with increased PET uptake in the pulmonary parenchyma have been shown to have active disease by virtue of changes in their pulmonary function.¹⁷² In this study, sarcoidosis patients with increased parenchymal PET uptake who were treated showed a significant improvement in their FVC and DL_{CO} , and those who were not treated showed a significant fall in DL_{CO} ; those without increased

PET parenchymal activity had no change in FVC and DL_{CO} without therapy, indicating inactive disease.¹⁷² In a study comparing PET to gallium scans, the PET scan was found to be more sensitive and reproducible.¹⁷³ Because the PET scan is more widely available and can be performed in 1 day rather than the 2 days necessary for gallium scanning, the PET scan is preferred, provided that there are no issues with reimbursement. Imaging of the heart for detection of cardiac sarcoidosis can be performed with either PET or magnetic resonance imaging (MRI) scanning¹⁷⁴; cardiac MRI appears to be more sensitive and specific.¹⁷⁵ However, cardiac MRI requires special expertise to interpret and is usually contraindicated once a defibrillator or pacemaker has been placed.

HEALTH-RELATED QUALITY OF LIFE

Sarcoidosis has been associated with impaired *health-related quality of life* (HRQOL),¹⁷⁶⁻¹⁷⁸ and treatment of sarcoidosis has been associated with changes in HRQOL.¹⁷⁸ However, the results of studies have been discordant. Corticosteroids have demonstrated improvement,¹⁷⁹ no change,¹⁸⁰ or worsening¹⁷⁷ in the short form 36, a general quality-of-life instrument. The Saint George Respiratory Questionnaire, which was originally developed as a measure of HRQOL in chronic obstructive pulmonary disease,¹⁸¹ has also been used for several interstitial lung diseases, including idiopathic pulmonary fibrosis and sarcoidosis.^{182,183} Improvements in the Saint George Respiratory Questionnaire results have been reported for patients with sarcoidosis-associated pulmonary hypertension who have been treated with pulmonary hypertension therapy.^{184,185} In addition, two sarcoidosis-specific quality-of-life instruments have been developed: the Sarcoidosis Health Questionnaire¹⁸⁶ and the King's Sarcoidosis Questionnaire.¹⁷⁶

Fatigue is a common complaint in sarcoidosis patients.^{187,188} It has been reported by more than half of sarcoidosis patients in both Europe and the United States.¹⁸⁹ Although fatigue is reported by patients with both pulmonary and extrapulmonary sarcoidosis, it is more common in the latter.¹⁹⁰ Fatigue may persist long after other evidence of disease has regressed.¹⁸⁸ There are several fatigue scales that are not specific for a particular disease^{187,190,191}; however, the Fatigue Assessment Scale is a sarcoidosis-specific fatigue questionnaire.¹⁹² The questionnaire appears to have a good correlation with general fatigue questionnaires in some^{191,193} but not in all¹⁹⁴ studies. The Fatigue Assessment Scale has been found to improve in sarcoidosis patients treated with infliximab.¹⁹⁵

Depression is a common underdiagnosed problem in sarcoidosis patients.^{196,197} The prevalence of depression ranged from 25% to 60% of the subjects and may contribute to a poorer quality of life.^{196,198} Consequently, a referral for a psychiatric or psychological evaluation and counseling should be considered for many sarcoidosis patients.

Sarcoidosis-associated pulmonary hypertension (SAPH) can develop from a variety of mechanisms, including left ventricular diastolic dysfunction, pulmonary arterial vasculitis, pulmonary veno-occlusive disease, pulmonary fibrosis, and hypoxia.¹⁹⁹ The overall incidence of pulmonary hypertension in sarcoidosis appears to be 5% to 15%.^{147,152,200,201} In patients with moderate to severe symptoms, the

Table 66-3 Organ Involvement in Sarcoidosis

	Charleston (%)	Cincinnati (%)
Female	66	71
African American	66	43
SPECIFIC ORGAN INVOLVEMENT		
Lungs	89	88
Eye	23	33
Skin	32	33
Liver	20	13
Neurologic	9	14
Cardiac	4	5

Organ involvement in more than 2700 patients seen at two large clinics.

Standardized criteria for diagnosis were the same in each clinic, and only definite or probable involvement was recorded.

Charleston data from Judson MA, Boan AD, Lackland DT: The clinical course of sarcoidosis: presentation, diagnosis, and treatment in a large white and black cohort in the United States. *Sarcoidosis Vasc Diffuse Lung Dis* 29:119–127, 2012. Cincinnati data are unpublished.

prevalence of pulmonary hypertension has been reported to be 50% or greater.^{148,202–204} Precapillary pulmonary hypertension is the most common cause of SAPH, but left ventricular diastolic dysfunction is present in a significant proportion of cases.^{201,204} The survival of patients with precapillary SAPH is significantly worse than for those with diastolic dysfunction.²⁰⁴

EXTRAPULMONARY SARCOIDOSIS

Sarcoidosis is a multiorgan disease. Pulmonary involvement has been reported in over 90% of cases in most large series.^{13,93,205} However, several other organs are commonly affected with the disease. Table 66-3 lists organ involvement as detected by two large clinics in the United States with a total of more than 2700 patients.²⁰⁵ Both of these groups used the same standardized criteria for organ involvement and listed only those organs with definite or probable disease.²⁰⁶ Patients may have undetected organ involvement. For example, liver biopsies performed in patients without symptomatic liver disease may still demonstrate granulomatous inflammation in up to half of the cases.^{121,207}

EYES

The eyes are involved in about a third of patient in the United States and Europe. Eye disease is more common in African Americans and in women.^{13,205} In Japan up to 80% of sarcoidosis patients have eye disease.²⁰⁸ Table 66-4 lists some of the more common ocular manifestations of sarcoidosis.²⁰⁹ It is recommended that all sarcoidosis patients undergo an ocular examination by a specialist at the time of initial evaluation.¹ Uveitis is the most common manifestation of ocular sarcoidosis and at times can be clinically silent. Anterior uveitis typically presents acutely, with pain, photophobia, lacrimation, and redness, but may have a more chronic course. Posterior uveitis is typically gradual in onset and is more likely to affect vision. Conjunctival nodules are another common, although usually asymptomatic, presentation. In fact, the diagnosis of sarcoidosis can sometimes be made with conjunctival biopsy, even in patients without any ocular symptoms. Patients with ocular

Table 66-4 Types of Eye Involvement in Sarcoidosis

Figure 66-13 Cutaneous sarcoidosis. Arm of patient with chronic cutaneous sarcoidosis demonstrating maculopapular lesions.

sarcoidosis may develop complications from eye involvement, such as sicca syndrome, glaucoma, and cataracts. Cataracts and glaucoma can also be a complication of either local or systemic corticosteroid treatment. Although less common, lacrimal gland enlargement is a characteristic finding. Vigilance for ocular involvement is extremely important, because approximately 10% of patients with sarcoid-associated uveitis develop blindness in at least one eye.

SKIN

Cutaneous involvement is also encountered in about a third of sarcoidosis patients.²¹⁰ Skin manifestations include maculopapular lesions, papules, hyperpigmentation, and hypopigmentation (Fig. 66-13).²¹¹ Lupus pernio is an indurated facial lesion that is specific for sarcoidosis (Fig. 66-14).²¹² It is more common in patients of African descent. It is usually chronic²¹³ and can be resistant to usual therapy.²¹⁴ Erythema nodosum, as noted earlier, is often, but not always, associated with a good prognosis.⁴⁹ In particular, patients of African descent with erythema nodosum will often have chronic disease.²¹⁵ Other cutaneous involvement may appear as patches, plaques, violaceous areas, localized alopecia, ichthyotic areas, subcutaneous nodules, ulcers, and pustules.

NERVOUS SYSTEM

Neurosarcoidosis develops in less than 10% of patients. Neurologic disease can involve the spinal cord or just the cranial nerves.^{216–218} The most sensitive method of detecting

Figure 66-14 Cutaneous sarcoidosis lesions. **A**, Lupus pernio. Violaceous nodular plaques on the nose, cheek and lip. **B**, Lupus pernio. Violaceous swelling of distal digits. **C**, Papular sarcoidosis. Multiple papules in a periorbital distribution. **D**, Cutaneous sarcoidosis presenting as pink indurated areas within and around a tattoo. (Adapted from Marchell RM, Judson MA: Chronic cutaneous lesions of sarcoidosis. *Clin Dermatol* 25:295–302, 2007.)

disease is MRI with gadolinium because neurologic lesions will often enhance.^{218,219} Spinal fluid analysis can be helpful, because it may demonstrate a lymphocytosis and elevated protein level.²¹⁹ An elevated level of ACE in spinal fluid has been reported to be specific for neurosarcoidosis, but a sensitivity as low as 50% has been reported.²²⁰ In patients with neurosarcoidosis, especially those who present as isolated neurosarcoidosis,²²¹ one has to consider multiple sclerosis.²²² Patients with sarcoidosis can develop optic neuritis, with or without uveitis.²²³ It is important to distinguish these patients from multiple sclerosis, because neurosarcoidosis patients will often improve with treatment, including with anti-tumor necrosis factor (TNF) treatments such as infliximab.^{223,224}

HEART

Sarcoidosis can directly cause an infiltrative cardiomyopathy with two major manifestations: arrhythmias and reduced ejection fraction. The detection of cardiac sarcoidosis can be difficult.²²⁵ The presence of cardiac symptoms, including palpitations and syncope, is a sensitive but not specific screening for sarcoidosis. Echocardiography and 24- to 48-hour cardiac monitoring are useful supplemental tests for screening.¹⁷⁴ Table 66-5 summarizes the prevalence, sensitivity, and specificity for cardiac sarcoidosis of screening tests by themselves or in combination.¹⁷⁴ Currently imaging with MRI and/or PET scanning is felt to be the most specific for diagnosing cardiac sarcoidosis.²²⁵ The arrhythmias, especially ventricular arrhythmias, remain a potential cause of death in cardiac sarcoidosis.²²⁶ However, implantable defibrillators have markedly reduced the mortality from this manifestation.^{227,228} Therefore patients with potential cardiac sarcoidosis should be screened for ven-

Table 66-5 Screening for Cardiac Sarcoidosis: Diagnostic and Prognostic Value of Outpatient Testing

Abnormalities on Baseline Testing	Prevalence	Sensitivity	Specificity
History of cardiac symptoms	12 (19%)	46%	95%
ECG	3 (5%)	8%	97%
Holter monitor	13 (21%)	50%	97%
Echocardiogram	8 (13%)	25%	95%
Any screening variable	29 (47%)	100%	87%
Two or more variables	7 (11%)	25%	97%
Three or more variables	1 (2%)	4%	100%
All variables abnormal	0 (0%)		

A study of 62 consecutive patients with sarcoidosis evaluated for cardiac sarcoidosis with symptoms (palpitations, presyncope, or syncope) and a series of tests. Based on cardiac MRI and PET scanning studies, 24 patients were diagnosed with cardiac sarcoid; the sensitivity and specificity of various screening variables individually or in combination are shown. ECG, electrocardiogram; MRI, magnetic resonance imaging.

tricular arrhythmias and evaluated by a specialist for the need for defibrillator implantation.^{228a}

EARS, NOSE, AND THROAT

The salivary glands can be involved in sarcoidosis, resulting in severe xerostomia, otitis media, vestibular symptoms, or hearing loss. Nasal and paranasal sinus involvement presents with nonspecific symptoms, including nasal congestion,

postnasal drip and sinus pressure, headaches, and infections. Lupus pernio, nasal deformities such as saddle nose deformity, and nasal mucosal abnormalities such as friability with crusting, bleeding, and submucosal nodules may accompany these symptoms. Rarely, the submucosal nodules may erode through the hard or soft palate, resulting in oral ulcerations or fistulous tracts. Other rare complications of nasal and sinus disease include epiphora (chronic tearing due to intranasal lacrimal tract outlet obstruction), anosmia (loss of the sense of smell due to direct involvement of the olfactory epithelium or obstruction of the olfactory cleft), and mass lesions with intraorbital or intracranial invasion. Definitive diagnosis relies on biopsy evidence of granulomatous inflammation and exclusion of other infections and inflammatory causes (e.g., fungal or mycobacterial infection, rhinoscleroma, or vasculitis). There are a number of management strategies for sinonasal sarcoidosis, depending on disease severity and location.

PAROTID GLAND

Parotid enlargement is a classic but rare disease feature. Heerfordt syndrome, or uveoparotid fever, is characterized by parotid enlargement with fever, facial palsy, and anterior uveitis.

LIVER AND SPLEEN

Liver involvement is common in sarcoidosis.²²⁹ The usual pattern seen in the serum chemistry results is an elevated alkaline phosphatase level and sometimes elevated transaminase levels.^{121,207} Imaging of the liver with contrast CT scan can be supportive of the diagnosis. Liver biopsy will usually detect granulomatous disease, even in patients with no symptoms or blood chemistry abnormalities.^{121,207,230} Splenic involvement is also rarely symptomatic, but is common, as determined by studies of fine-needle aspiration biopsies. Rarely, splenomegaly can be massive and may cause thrombocytopenia or other cytopenias.

JOINTS

Arthralgias are common in patients with Löfgren syndrome; other forms of sarcoidosis less commonly demonstrate joint involvement. Arthralgias are noted by 25% to 39% of patients, but deforming arthritis is rare. Between 3% and 13% of patients display bony involvement, although the increasing use of MRI may increase future estimates of the frequency of osseous sarcoidosis. Classically, if the bones are involved, plain radiographs or MRI will demonstrate bone cysts in the phalanges, although virtually any bone can be affected.

Symptomatic muscle involvement, characterized by nodules, acute myositis, or chronic myopathy, is rare; however, in systemic sarcoidosis without clinical manifestations of muscle disease, 20% to 75% of cases are found to have granulomas on muscle biopsy.

PERIPHERAL LYMPH NODES

Hilar and mediastinal lymphadenopathy is common (up to 90% of patients). However, peripheral lymphadenopathy is

not as common (5% to 30%). The nodes are typically nontender, mobile, and located in the cervical, axillary, epitrochlear, and inguinal regions.

ENDOCRINE GLANDS

Hypercalcemia or hypercalciuria has been reported in up to 30% of sarcoidosis patients.^{231,232} The most common mechanism is from excessive levels of 1,25-dihydroxyvitamin D due to autonomous 1- α -hydroxylase activity.^{233,234} Levels of 1,25-dihydroxyvitamin D may be elevated despite low levels of 25-hydroxyvitamin D.²³¹ There are other causes of hypercalcemia in sarcoidosis, including hyperparathyroidism.²³¹ Hypercalcemia in sarcoidosis patients can be associated with renal failure, which may reverse with treatment of the hypercalcemia.²³⁵

BLOOD

Hematologic abnormalities are seen in up to 40% of patients (e.g., anemia, leukopenia, lymphopenia, or a combination of these). Bone marrow involvement or splenic enlargement with platelet destruction may rarely cause thrombocytopenia.

TREATMENT OF SARCOIDOSIS

Most patients with sarcoidosis show evidence of disease remission within 3 years of diagnosis with few or no long-term consequences. However, up to one third of patients have persistent disease, which causes significant organ impairment. Few patients die from sarcoidosis (<5%), with death usually the result of cardiac or neurologic involvement or of respiratory failure due to pulmonary fibrosis.

The treatment of sarcoidosis requires consideration of sarcoidosis-related inflammation, the complications of the disease, and the complications of therapy. Table 66-6 lists these aspects of the disease and potential treatments, when they have been reported, with the level of evidence to support their use in sarcoidosis.^{236,237}

ANTI-INFLAMMATORY MEDICATIONS

Because sarcoidosis patients are frequently asymptomatic and many will have spontaneous resolution of their sarcoidosis within 6 months of diagnosis,¹⁵⁸ not all patients require initial therapy.^{158,238,239} The usual decision to treat patients is based on symptoms and, with regard to pulmonary sarcoidosis, when there is a concomitant decline in pulmonary function.²³⁸

Corticosteroids remain the most widely used, well-documented, and most effective treatment for sarcoidosis.^{5,240,241} The reported initial dose of corticosteroids varies widely. McKinzie and colleagues have found that, in some patients, there was a significant improvement in FVC in less than a month with an average daily dose of prednisone of 20 mg.²⁴² Once the patient has had improvement, the dose of drug is usually tapered to minimize toxicity but to maintain the benefit from the initial induction of response. In some cases, patients may relapse when treatment is reduced, requiring an increase in dosage.²⁴³ Patients

Table 66-6 Treatment for Sarcoidosis*

Anti-inflammatory treatment	
Acute disease	
Glucocorticoids	1A
Hydroxychloroquine	2B

*NOTE: The grading scheme classifies recommendations as strong (grade 1) or weak (grade 2), according to the balance among benefits, risks, burdens, and possibly cost, and the degree of confidence in estimates of benefits, risks, and burdens. The system classifies quality of evidence as high (grade A), moderate (grade B), or low (grade C) according to factors that include the study design, the consistency of the results, and the directness of the evidence.²³⁷

may also relapse after the drug is withdrawn, so a slow withdrawal over the course of months is usually recommended.²⁴⁴ Even those patients treated with glucocorticoids for 2 or more years have at least a 50% chance of relapse when drug is withdrawn.^{245,246}

Patients who do not respond to the equivalent of prednisone 40 mg daily are considered refractory to standard treatment and can be considered for alternative therapy. However, such patients are relatively rare.

For patients who are started on therapy, a significant percentage will require long-term treatment beyond 2 years.^{158,238,239,244,247} Corticosteroid-sparing agents and alternative agents are often considered in these patients because significant cumulative toxicities from corticosteroids are common. For many of the nonsteroidal immunosuppressive agents, there are evidence-based recommendations for monitoring patients while being treated for pulmonary disease.²⁴⁸

The antimalarial agents, chloroquine and hydroxychloroquine, have been reported to be effective in treating certain aspects of extrapulmonary disease,^{249,250} such as cutaneous and sinonasal disease.^{249,251} They have also proved useful in treating hypercalcemia²⁵² and may be more effective in treating sarcoidosis-associated fatigue than other anti-inflammatory agents.¹⁸⁹ The major toxicity encountered with antimalarial agents has been ocular. Hydroxychloroquine appears to have a lower rate of ocular toxicity. However, routine screening is still recommended.²⁵³⁻²⁵⁵ For most patients, 400 mg a day of hydroxychloroquine appears to be safe. In the most recent recommendations, the dose needs to be modified only for those of short stature.²⁵⁵

Methotrexate is a commonly used steroid-sparing cytotoxic agent for sarcoidosis.^{240,256} Methotrexate has been shown to be effective in remitting and persistent disease. It has also been shown to be effective in ocular,^{209,257} cutaneous,²⁵⁸⁻²⁶⁰ sinus,^{261,262} and neurologic disease.^{263,264} A major potential toxicity of methotrexate and other cytotoxic drugs is bone marrow suppression. The effect is dose dependent. There are evidence-based and expert opinion recommendations for monitoring patients while receiving methotrexate therapy.^{248,265}

Azathioprine is another cytotoxic agent commonly used in chronic sarcoidosis. Limited data suggest that it is as effective as methotrexate but results in greater toxicity.²⁶⁶ It has been shown to be effective in pulmonary²⁶⁷ and extrapulmonary disease.^{261,268,269} A recent report of increased morbidity and mortality for patients with idiopathic pulmonary fibrosis receiving azathioprine suggests that the full dosage of the drug should be used with caution in patients with advanced fibrotic disease.²⁷⁰

Leflunomide is an antimetabolite similar in action to methotrexate originally developed for treating rheumatoid arthritis.²⁷¹ It has been reported to be effective in treating sarcoidosis either alone or in combination with methotrexate.^{272,273} Compared to methotrexate, leflunomide has less gastrointestinal toxicity, although it has a similar rate of liver function test result abnormalities.²⁷¹ Leflunomide can produce pulmonary toxicity, but at a lower rate than with methotrexate.^{274,275} Leflunomide can also cause a peripheral neuropathy, which usually resolves with discontinuation of the drug.^{276,277}

Mycophenolate analogues have been increasingly employed to treat inflammatory lung diseases.^{278,279} They have been reported to be as effective as a steroid-sparing agent for those with persistent disease, especially neurosarcoidosis.^{280,281} Whereas mycophenolate treatment has less bone marrow toxicity and hepatotoxicity, it is still associated with significant gastrointestinal and infectious complications.²⁸²

Infliximab is a chimeric monoclonal antibody directed against TNF. It was first reported to be effective in treating refractory sarcoidosis in 2001.^{283,284} The drug has been widely used for various forms of refractory disease, including pulmonary, skin, eye, and neurologic disease.²⁸⁵⁻²⁸⁹ Two double-blind placebo-controlled trials have shown a benefit of infliximab when used in addition to maintenance therapy.^{159,180} The drug has also proved to be effective for some patients with extrapulmonary disease.²⁹⁰ In a large retrospective study of patients with lupus pernio, infliximab

was superior to all other treatment options.²¹⁴ It has also proved to be useful in treating refractory neurosarcoidosis.^{281,291} Infliximab is not a cure for sarcoidosis. Adverse effects of the drug may be considerable, and a high rate of relapse has been reported when the drug is withdrawn within a year of treatment.²⁹²

The toxicity of infliximab includes an allergic reaction to the chimeric antibody, which can manifest as an acute reaction, including anaphylaxis, vasculitis, or a subacute, lupus-like reaction.²⁹³ In addition, along with the other anti-TNF antibodies, infliximab has also been associated with a high risk for the reactivation of tuberculosis.²⁹⁴ The risk appears to be lower with the TNF receptor antagonist etanercept.^{294,295} Adhering to guidelines for screening and treating latent tuberculosis can significantly reduce this risk for reactivation.²⁹⁶ Testing for latent tuberculosis with skin testing may not be adequate in sarcoidosis, because anergy is a common problem.²⁹⁷ An interferon- γ release assay seems to be more reliable for screening for latent tuberculosis in anergic or immunosuppressed patients.²⁹⁸ The anti-TNF treatments may be contraindicated in patients with advanced congestive heart failure because of an apparent increased mortality rate in such patients treated with infliximab.²⁹⁹ However, infliximab has been used successfully in treating cardiomyopathy due to sarcoidosis.^{56,300,301} Finally, there may be an increased risk for malignancy with the use of anti-TNF agents. In rheumatoid arthritis, a meta-analysis found an increase in nonmelanoma skin cancers only.³⁰² However, another study suggested a potential increased risk for lymphoma, although the relative risk was not significantly different from that for controls.³⁰³ Thus the risk for developing cancer in sarcoidosis patients treated with anti-TNF therapy is unknown, and one should remain cautious regarding this risk when using this class of drugs.

Adalimumab, a totally humanized anti-TNF antibody, has been reported to be effective in treating some sarcoidosis cases.^{289,304-306} Compared to infliximab, it appears to have a lower response rate and takes longer to demonstrate effectiveness.²⁸⁸ This may be due to the relatively lower doses of drug initially used. When used at a higher induction and maintenance dose, for example, adalimumab has been shown to be more effective in treating Crohn disease.³⁰⁷ This higher dose of the anti-TNF antibody may be necessary to achieve clinical response in sarcoidosis, but it remains unclear how often these increased doses need to be employed.³⁰⁸ A potential dose-dependent effect may explain the failure of a recently completed trial of golimumab, another humanized monoclonal anti-TNF antibody.

Etanercept is a TNF receptor antagonist and has been reported to be effective in some cases of refractory sarcoidosis.³⁰⁹ However, the drug was not found to be effective in an open-label trial of pulmonary sarcoidosis³¹⁰ or in a placebo-controlled double-blind randomized controlled trial of ocular sarcoidosis.³¹¹

Interestingly, patients treated with anti-TNF therapy can develop a granulomatous disease that is indistinguishable from sarcoidosis.^{312,313} The mechanism of this reaction is unknown, but possible mechanisms include rebound TNF production or alteration of the function of Treg cells.³¹⁴ As noted earlier, abnormalities of Treg cells have been described in sarcoidosis.^{60,61} Of note, there are several new anti-inflammatory therapies being evaluated in sarcoidosis.⁵

MANAGEMENT OF EXTRAPULMONARY DISEASE

In general the treatment of extrapulmonary disease is similar to the treatment of pulmonary disease. However, there are a few special considerations. For ocular disease, local therapy with topical steroids, periocular steroid injections, and steroid implants may be sufficient to control disease.²⁰⁹ However, use of corticosteroids may cause cataract formation or glaucoma. Therefore the use of a cytotoxic agent, such as methotrexate, is considered desirable early in the management of chronic ocular sarcoidosis.^{257,289} For cutaneous sarcoidosis, patients may often respond to hydroxychloroquine or local steroid therapy.^{251,315} However, lupus pernio responds significantly more often to infliximab than to corticosteroid or cytotoxic therapy.³¹⁶ Neurologic disease often requires more intense treatment with either higher doses of corticosteroids and/or cytotoxic treatments.²⁶³ Anti-TNF treatment may be particularly helpful in the treatment of refractory neurosarcoidosis.^{281,317}

ANTIFIBROTIC THERAPY

Patients with significant pulmonary fibrosis from sarcoidosis have an increased mortality.¹⁶³ To date there is limited understanding of the pathophysiologic mechanisms that underlie fibrosis, a lack of potential therapies for pulmonary fibrosis in general, and no specific therapy reported to be effective for the fibrotic component of sarcoidosis.³¹⁸

SUPPORTIVE CARE

Supportive care is a mainstay of therapy, especially for patients with severe dyspnea, hypoxemia, and pulmonary hypertension (see later).³¹⁹ Supportive therapy, as is common in other fibrotic lung diseases, includes facilitation of mucociliary clearance and treatment of infections associated with bronchiectasis, supplemental oxygen, and pulmonary rehabilitation when appropriate.³²⁰

MANAGEMENT OF COMPLICATIONS OF SARCOIDOSIS

Pulmonary Hypertension

For precapillary *sarcoidosis-associated pulmonary hypertension* (SAPH), several pulmonary hypertension agents have been studied. Table 66-7 lists some of the studies specifically designed to determine the efficacy of treatment. These include the prostanoids, including intravenous prostacyclin^{321,322} and inhaled iloprost.¹⁸⁴ Long-term use of intravenous epoprostenol was associated with prolonged clinical improvement in some cases.³²¹ The endothelin receptor antagonists have also been reported to be safe in treating SAPH.^{185,323,324} A double-blind, placebo-controlled study demonstrated significant improvement of pulmonary hemodynamics for SAPH patients treated with bosentan but not for those treated with placebo.³²⁵ Sildenafil has also been shown to improve hemodynamics in patients with SAPH.³²⁶

For several of the studies cited in Table 66-7, the response to treatment for SAPH was in pulmonary hemodynamics and/or quality of life.^{184,185,326} In part that was because the

Table 66-7 Treatment of Sarcoidosis-Associated Pulmonary Hypertension

Class	Therapy	Significant improvement	Improvement Seen in Some Cases
Prostanoids	Epoprostenol ³²² Epoprostenol ³²¹ Iloprost ¹⁸⁴		Improved hemodynamics Improved hemodynamics Improved hemodynamics and HRQOL
Endothelin receptor antagonists	Bosentan ³²⁵ Ambrisentan ¹⁸⁵	Improved hemodynamics	Improved HRQOL
Phosphodiesterase-5 inhibitors	Sildenafil ³²⁶		Improved hemodynamics

HRQOL, health-related quality of life; 6MWD, 6-minute walk distance.

studies examined patients after only a relatively short period, usually 4 months. In one study that evaluated SAPH patients after more prolonged therapy, there was not only improvement in hemodynamics, but also improvement in 6MWD.³²³ However, that improvement in 6MWD was seen only in those with mild to moderate restrictive disease and was unusual in those patients with a FVC of less than 50% of predicted value.

Fatigue

As noted earlier, fatigue is a common manifestation of sarcoidosis.¹⁸⁷ Fatigue can be associated with several factors, including diabetes, depression, and sleep apnea.^{327,328} Sleep apnea is a common problem in sarcoidosis patients, especially in those patients who have been treated with glucocorticoids.³²⁸⁻³³⁰ However, even after treatment of sleep apnea, fatigue may persist.¹⁹³

Fatigue may be severely debilitating but is not life-threatening. As a result, the benefits associated with treatment of fatigue should always be weighed against the risks associated with the side effects. Neurostimulants such as methylphenidate have been reported to be effective in treating sarcoidosis-associated fatigue.³³¹ In a double-blind, placebo-controlled crossover trial of dexamethylphenidate, sarcoidosis-associated fatigue was 30% lower during active treatment than during placebo treatment.¹⁹¹ A limitation of methylphenidate is the short half-life of the drug, often requiring an afternoon dose, which may lead to insomnia. The drug armodafinil is a neurostimulant-like drug that, in a double-blind, placebo-controlled crossover trial, was found to reduce fatigue significantly more than placebo.¹⁹³

There is a relationship between small fiber neuropathy and fatigue.³³² Several agents have been used with varying success in sarcoidosis-associated small fiber neuropathy. Neuropathic agents are often the initial drugs of choice. These agents, however, have limited efficacy. In refractory cases the anti-TNF agents should be considered. Intravenous gamma globulin treatment was reported to be effective in one small retrospective series.³³³ Other treatments are currently being studied.³³⁴

Aspergilloma

Fungal infections, especially aspergilloma, are a serious complication of advanced fibrotic sarcoidosis and are usually associated with immunosuppressive therapy.^{6,163,335-337}

Aspergillomas may lead to fatal hemoptysis. The risks and benefits of medical and surgical therapy vary with the manifestations of disease and the patient's pulmonary status. Therefore the approach to therapy must be individualized. In patients with good pulmonary function, surgical resection can be offered to prevent or treat potentially life-threatening hemoptysis and is usually curative. The medical treatment of aspergillomas includes azole therapy.^{6,338,339} The evidence regarding the efficacy of long-term antifungal therapy for chronic cavitary pulmonary aspergillosis is based upon small case series and open-label noncomparative studies.^{338,340} Limited data suggest that intracavitary amphotericin may be effective on a short-term basis in treating selected cases of aspergillomas in sarcoidosis patients.³⁴¹

Bone Health

Because sarcoidosis patients often have high levels of vitamin 1,25-dihydroxyvitamin D there usually is no reason for supplementation of vitamin D.³⁴² However, bisphosphonates can improve osteopenia or osteoporosis in sarcoidosis patients.³⁴³

Lung Transplantation

Lung transplantation has been successfully performed in sarcoidosis patients.³⁴⁴ Patients may develop granulomas in the transplanted lung,³⁴⁵ but this does not generally alter the clinical outcome of transplant recipients, because post-transplant immunosuppression is often adequate treatment for the sarcoidosis.³⁴⁶ One should focus on treating superimposed infections, because they are common complications of the bronchiectasis seen in fibrotic sarcoidosis and they may be one of the events leading to acute decompensation.³⁴⁷

Key Points

- Sarcoidosis is characterized by an enhanced granulomatous response to an unknown antigen.
- Although many patients with sarcoidosis have resolution of their disease within 2 years, a significant proportion have chronic disease—with roughly a quarter of all patients still requiring systemic therapy more than 2 years after diagnosis.

- Genetic polymorphisms have been shown to be associated with clinical outcome in some cases.
- The diagnosis of sarcoidosis relies on recognition of a clinical pattern consistent with disease, exclusion of other conditions that can cause granulomatous inflammation and, in most cases, a biopsy demonstrating granulomas.
- Identification of extrapulmonary disease is important not only to identify other potential causes of morbidity in sarcoidosis but also to help bolster confidence in the diagnosis.
- Fatigue, chest discomfort, and depression are conditions that lead to poor quality of life for patients with chronic sarcoidosis.
- Systemic treatment of sarcoidosis, usually initially with glucocorticoids, is indicated when the patient has symptoms. Steroid-sparing agents are most useful for patients with chronic disease or those encountering toxicity with glucocorticoids.

INTRODUCTION

This chapter discusses *diffuse alveolar hemorrhage* (DAH) and includes other rare infiltrative disorders of the lung. DAH is a serious condition characterized by widespread intra-alveolar hemorrhage that originates from the pulmonary microcirculation (arterioles, capillaries, and venules). DAH can be seen in many different diseases, often as the presenting manifestation.

The second section of the chapter discusses several rare infiltrative disorders of the lung, including neurofibromatosis, Hermansky-Pudlak syndrome, dyskeratosis congenita, Gaucher disease, Niemann-Pick disease, and pulmonary alveolar microlithiasis.

DIFFUSE ALVEOLAR HEMORRHAGE

Unlike the more common forms of pulmonary hemorrhage that result from focal lesions (e.g., necrotizing pneumonia, bronchitis, bronchiectasis, malignancy, pulmonary infarction, arteriovenous malformation), DAH affects the majority of the alveolar capillary surface. DAH is a medical emergency that often results in acute respiratory failure and death. Pulmonologists must be prepared to identify DAH promptly, diagnose the underlying disease that is causing it, and institute appropriate medical therapy.

DEFINITION

DAH is defined on clinical grounds: diffuse pulmonary opacities with varying degrees of respiratory failure, a falling hemoglobin level, and progressively bloody return (or with increasing red blood cell counts) on sequential *bronchoalveolar lavage* (BAL). The pathologic process is characterized by the intra-alveolar accumulation of erythrocytes (Fig. 67-1). There can be evidence of chronicity with the accumulation of intra-alveolar hemosiderin-containing macrophages, erythrophagocytosis, and collections of free interstitial hemosiderin,¹⁻³ findings that help distinguish DAH from acute biopsy-related bleeding. Other histologic features of DAH include hyperplasia of the type II alveolar epithelial lining cells, intra-alveolar organization (organiz-

ing pneumonia), mononuclear cell infiltration of the alveolar interstitium, and small thrombi in the alveolar capillaries and venules.¹⁻⁵

Patients with DAH may demonstrate neutrophilic inflammation of the alveolar interstitium known as pulmonary or alveolar *capillaritis* (Fig. 67-2).⁶ Capillaritis is commonly associated with endothelial edema, injury, and localized fibrinoid necrosis.⁴ Characteristically there is infiltration of the alveolar septa with neutrophils, many of which are undergoing leukocytoclasia and appear fragmented and pyknotic. Fragmentation of these cells leads to accumulation of nuclear dust in the lung parenchyma. Capillaritis is a small vessel vasculitis of the lung and is central to the pathogenesis of many cases of DAH. This small vessel injury and necrosis leads to the loss of integrity of the shared epithelial-endothelial alveolar basement membrane, resulting in extravasation of red blood cells into the alveolar lumina. DAH can also result from all causes of *diffuse alveolar damage* (DAD) (i.e., cytotoxic drug, allogeneic [bone marrow transplantation]), and can also result from bland (noninflammatory) injuries (i.e., mitral stenosis).

CLINICAL PRESENTATION

History and Physical Examination

The clinical presentation of DAH includes hemoptysis, alveolar opacities on chest radiograph, and anemia.⁷ However, there are cases that show only one or two of these features; the absence of classic features does not exclude DAH. In up to 33% of cases, hemoptysis is initially absent. Other symptoms are nonspecific (e.g., dyspnea, cough, chest pain, fever), although in some cases, disease-specific symptoms (e.g., sinusitis, rash, arthritis) may be present. In general, symptoms are usually of short duration, present from days to several weeks, and may be recurrent. The lung examination is nonspecific, with inspiratory crackles common but not universal. There may also be physical findings suggesting a systemic disease.

Radiology and Laboratory Evaluation

Laboratory evaluation usually reveals anemia and leukocytosis. Serum creatinine levels may be elevated. BAL reveals a bloody return that, with each aliquot returned from the same location, becomes progressively more bloody

Figure 67-1 Histopathologic findings of diffuse alveolar hemorrhage. **A**, In acute diffuse alveolar hemorrhage, the alveoli show filling and distention by red blood cells admixed with fibrin. **B**, Chronic alveolar hemorrhage shows numerous hemosiderin-filled macrophages within air spaces. The alveolar septa may show mild fibrosis. (Courtesy Dr. Kirk Jones, University of California, San Francisco.)

Figure 67-2 Histopathologic findings of diffuse alveolar hemorrhage accompanied by pulmonary capillaritis. Capillaritis is identified by accumulation of neutrophils (see *arrows*) within alveolar septa with accompanying fibrinoid necrosis and adherent alveolar fibrin within air spaces (*arrowheads*). (Courtesy Dr. Kirk Jones, University of California, San Francisco.)

Figure 67-3 Sequential bronchoalveolar lavage (BAL) showing increasing bloody appearance diagnostic of diffuse alveolar hemorrhage. These BAL, sequential in order from left to right, were obtained from the same location of the lung in a patient with granulomatosis with polyangiitis (Wegener granulomatosis). (Courtesy Dr. Sixto Arias, Johns Hopkins University.)

(Fig. 67-3). BAL shows increased sequential red blood cell counts even in patients who do not present with hemoptysis. On examination of the sediment, there is a predominance of red blood cells and hemosiderin-containing macrophages.

The chest radiograph in DAH shows varying degrees of diffuse alveolar opacities (Fig. 67-4; see eFigs. 60-3A, 60-9A, 60-10A, and Fig. 91-4A).⁸ High-resolution computed tomography (HRCT) imaging is more sensitive for radiographic abnormalities and generally shows bilateral ground-glass opacities or patchy consolidation, and occasionally centrilobular nodules. Nonetheless, it is important to recognize that the HRCT appearance of pulmonary hemorrhage is variable and not specific for a particular cause (Fig. 67-5; see eFigs. 60-3B-E, 60-9B-E, 60-10B-E, and Fig. 91-4B-D). With recurrent and chronic disease, reticulation may appear, providing evidence of interstitial fibrosis. Interlobular septal thickening (Kerley B lines) (eFig. 67-1) may occasionally be present in cases of mitral stenosis and pulmonary veno-occlusive disease. There are reports of an obstructive lung disease developing after recurrent episodes of DAH secondary to alveolar capillaritis.

Physiology

If measured, there are restriction and gas exchange abnormalities, particularly in chronic cases. In acute DAH an increase in the *diffusing capacity for carbon monoxide* (DL_{CO}) is often present, attributed to the increased binding of carbon monoxide to intra-alveolar hemoglobin.⁹ This will generally resolve in 48 to 72 hours, as hemoglobin is degraded into hemosiderin.¹⁰ Varying degrees of hypoxemia result from the ventilation-perfusion abnormalities produced by the alveolar hemorrhage, and patients often require ventilatory support.

CLASSIFICATION SCHEMA

There is no consensus classification schema for DAH, although clinical, histopathologic, and etiologic approaches have all been suggested.^{7,11} One approach is presented here

Figure 67-4 Diffuse alveolar hemorrhage (DAH). Chest radiographs show diffuse alveolar opacities in a patient with microscopic polyangiitis (**A**) and in a patient with granulomatosis with polyangiitis (Wegener granulomatosis) (**B**).

(Table 67-1). The various causes of DAH are diverse; any source of injury to the alveolar microcirculation may contribute. The pathogenesis of DAH due to capillaritis is thought to be due to one of the following scenarios: (1) the direct effects of autoantibodies on the alveolar capillary endothelium, as in *granulomatosis with polyangiitis* (GPA; Wegener granulomatosis) or *microscopic polyangiitis* (MPA), (2) the effects of antibody directed against the alveolar basement membrane (e.g., Goodpasture syndrome or *anti-glomerular basement membrane antibody* [ABMA] disease), (3) immune complex-mediated injury (e.g., *systemic lupus erythematosus* [SLE], Henoch-Schönlein purpura), or (4) direct alveolar injury.¹²

The most common causes of DAH are the systemic vasculitides, in particular GPA (Fig. 67-6). Other vasculitides are also implicated, including MPA and isolated pulmonary capillaritis. A review of 34 cases of DAH found that vasculitis accounted for about half of the cases, followed by Goodpasture syndrome (13%), *idiopathic pulmonary hemosiderosis* (IPH; 13%), and connective tissue disease (13%).¹

DIAGNOSTIC APPROACH

There are two steps to the diagnosis of DAH: identification of DAH and identification of its underlying cause. Both are essential to the timely evaluation of this life-threatening condition.

Diagnosis of Diffuse Alveolar Hemorrhage

The diagnostic considerations for patients presenting with DAH are broad. A thorough history and physical examination looking for evidence of potential associated conditions (e.g., connective tissue disease, symptoms/signs of systemic vasculitis, anticoagulant medications) is essential, and initial studies should include a HRCT scan of the chest, complete blood count, and examination of the urine sediment. If DAH is a possibility, fiberoptic bronchoscopy should be performed immediately.

Bronchoscopy with BAL is essential to the accurate identification of DAH. Sequential BAL specimens should be obtained and sent for cell count and differential, with an increasing red blood cell count considered consistent with the diagnosis. Quantitative scoring of the hemosiderin concentration in alveolar macrophages obtained by BAL cytologic examination has a sensitivity for the diagnosis of DAH as well.¹³ Importantly, BAL serves to rule out other diagnostic considerations such as infection, acute hypersensitivity pneumonitis, acute eosinophilic pneumonia, and pulmonary alveolar proteinosis.

Diagnosis of Underlying Cause

Once DAH is identified, the underlying cause must be determined. Table 67-2 summarizes the differential clinical and laboratory features of some of the more common causes of DAH. In some cases, the cause is clear (e.g., history of SLE, drug exposure). In others, a detailed laboratory evaluation is required. The presence of proteinuria and an abnormal urinary sediment (red blood cells and red blood cell casts) suggests an underlying glomerulonephritis consistent with the diagnosis of systemic vasculitis, Goodpasture syndrome, some connective tissue diseases, or rarely infection.^{13a} Vasculitis is associated with the presence of *antineutrophil cytoplasmic antibodies* (ANCA) directed against either proteinase 3 (*cytoplasmic ANCA* [c-ANCA]) or myeloperoxidase (*perinuclear ANCA* [p-ANCA]).¹⁴ Elevation of the c-ANCA level is seen in GPA, whereas elevation of p-ANCA is seen with MPA, pauci-immune glomerulonephritis, eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome), and sometimes isolated pulmonary capillaritis. However, there can be crossover.¹⁵

The diagnosis of Goodpasture syndrome is established by the presence of serum ABMA. DAH due to SLE is accompanied by reduced serum complement levels as well as the presence of antinuclear and native anti-DNA antibodies in the serum. Henoch-Schönlein purpura is characterized by the formation of *immunoglobulin A* (IgA) immune complexes present in the circulation and also bound to tissue.¹⁶

Role of Surgical Lung Biopsy and Renal Biopsy

For the diagnosis of DAH, BAL is generally sufficient. For identifying the underlying cause of the DAH, clinical and serologic findings are usually sufficient¹; surgical lung biopsy may be useful but is often nonspecific. However,

Figure 67-5 High-resolution CT (HRCT) appearance of diffuse alveolar hemorrhage (DAH). Axial chest CT images in different patients with various causes for DAH showing the variable CT manifestations of pulmonary hemorrhage. The features of DAH on HRCT are nonspecific and can be seen with any cause. **A**, Patchy, geographic ground-glass opacity in a patient with granulomatosis with polyangiitis (GPA) (Wegener granulomatosis). **B**, Vague, extensive multifocal ground-glass opacity in a patient with systemic lupus erythematosus. **C**, Dense consolidation with air bronchograms in a patient with microscopic polyangiitis. **D**, Consolidation and ground-glass opacity with a background of linear opacities representing interlobular septal thickening (arrowheads) in an over-anticoagulated patient undergoing antiplatelet therapy. **E**, Hazy ground-glass opacity in a patient with hemosiderin-laden macrophages on bronchoalveolar lavage, with presumed idiopathic hemosiderosis. **F**, Extensive peribronchovascular thickening and peribronchial consolidation and ground-glass opacity in a patient with GPA. Solid centrilobular nodules can also be a manifestation of pulmonary hemorrhage. (Courtesy Michael Gotway, MD.)

surgical lung biopsy should be considered for isolated DAH without an obvious cause.

When serologic findings are equivocal and vasculitis or Goodpasture syndrome is under consideration, renal biopsy may be appropriate because these conditions are more easily confirmed by kidney biopsy, even in the absence of clinically evident renal involvement.¹⁷ Moreover, renal biopsy may provide useful information regarding the activity and chronicity of renal involvement that may help guide therapy.

Therapeutic Approach

The most important first step in management is to identify the underlying cause and begin specific treatment when available, for example, by stopping suspected drugs or expo-

sure, treating infection, and reversing excess anticoagulation. Patients with severe hemoptysis require general supportive therapy that is based on the degree of bleeding.

Systemic glucocorticoids, with additional immunosuppressive therapy, are the mainstay of therapy for the DAH syndrome associated with systemic vasculitis, connective tissue disease, ABMA disease (Goodpasture syndrome), and isolated pulmonary capillaritis. The common approach is to begin intravenous pulse methylprednisolone (500 to 1000 mg in divided doses daily) for up to 5 days followed by gradual tapering and then maintenance on an oral preparation. The decision to add immunosuppressive therapy (cyclophosphamide or azathioprine) is dependent upon the severity of the illness, the responsiveness to glucocorticoids, and the underlying disease. Our practice is to begin

intravenous cyclophosphamide (0.75 g/m² if renal function is relatively normal). Careful attention must be given to the nadir of the peripheral white blood cell count. Oral therapy is usually started in approximately 2 weeks if neutropenia does not develop.

Plasma exchange is used in the treatment of DAD associated with ABMA disease or occasionally for refractory vasculitis syndromes or DAH associated with a connective tissue disease.¹⁸ A role for intravenous immunoglobulin or rituximab in patients with DAD remains to be defined. *Recombinant activated factor VII* (rFVIIa) has been used with variable success.^{18a-18c}

Table 67-1 Causes of Diffuse Alveolar Hemorrhage

VASCULITIS

Granulomatosis with polyangiitis (Wegener granulomatosis)

DIFFUSE INFILTRATIVE LUNG DISEASES

SPECIFIC CAUSES

Vasculitis (see Chapter 60)

Granulomatosis with Polyangiitis (Wegener Granulomatosis). GPA is a systemic vasculitis that commonly involves the upper and lower respiratory tracts and kidneys. Other organs (e.g., eyes, skin) may be involved. DAH secondary to pulmonary capillaritis can either complicate an established case of GPA or represent the initial manifestation of the disease. Pulmonary capillaritis can be the sole pulmonary parenchymal histologic finding, or it can be seen in combination with the more typical pathologic

Figure 67-6 Causes of diffuse alveolar hemorrhage. A retrospective review of 34 cases of diffuse alveolar hemorrhage found systemic vasculitis to be the most common cause (14 cases: 5 definite granulomatosis with polyangiitis [Wegener granulomatosis], 6 probable, and 3 unclassifiable), followed by unclassifiable pulmonary renal syndromes (5 cases), Goodpasture syndrome (ABMA disease) (4 cases), idiopathic pulmonary hemorrhage (IPH) (4 cases), connective tissue disease (CTD) (4 cases: 2 systemic lupus erythematosus, 1 rheumatoid arthritis, 1 juvenile rheumatoid arthritis), and other rare causes (3 cases: 2 idiopathic glomerulonephropathy, 1 immunoglobulin A nephropathy). ABMA, anti-glomerular basement membrane antibody. (Data from Travis WD, Colby TV, Lombard C, Carpenter H: A clinicopathologic study of 34 cases of diffuse pulmonary hemorrhage with lung biopsy confirmation. *Am J Surg Pathol* 14:1112–1125, 1990.)

Table 67-2 Clinical Differentiation of Common Diffuse Alveolar Hemorrhage Syndromes

Syndrome	Renal	Arthritis	Skin	ANA	dsDNA	C	ABMA	c-ANCA (PR3)	p-ANCA (MPO)	Histopathology; IF

ABMA, anti-glomerular basement membrane antibody; ANA, antinuclear antibody; C, complement; c-ANCA (PR3), cytoplasmic antineutrophil cytoplasmic antibody (anti-proteinase 3); dsDNA, anti-double-stranded DNA antibody; IF, immunofluorescence; IgG, immunoglobulin G; NI, normal; p-ANCA (MPO), perinuclear antineutrophil cytoplasmic antibody (antimyeloperoxidase).

features of GPA. Surgical lung biopsies from 87 patients with GPA revealed capillaritis in 31%, but in only 3 was it an isolated finding.⁵ In another series, capillaritis was present in 17% of 35 patients, but never as an isolated finding.¹⁹ In a postmortem study of 22 patients, capillaritis was the sole histologic feature in 3 and was seen in conjunction with the more typical granulomatous vasculitis in 7 cases.²⁰ The typical histologic features of GPA are granulomatous inflammation, small and medium vessel vasculitis, and parenchymal geographic necrosis. When DAH is present alone (see eFig. 60-3), without the characteristic histologic features, sinusitis (see eFig. 60-7), or nodular/cavitary lung lesions (see eFigs. 60-1, 60-2, 60-4, and 60-5), differentiation from MPA is difficult.

The specific diagnosis depends on the ANCA pattern, with c-ANCA suggesting the diagnosis of GPA. The characteristic histologic and clinical features of GPA may appear months to years after the initial presentation of DAH and capillaritis.²¹ Circulating endothelial cells are present in GPA and MPA. The presence of circulating endothelial cells may serve as a novel marker of active ANCA-positive vasculitis.²²

Alveolar hemorrhage is often subclinical and recurrent in GPA (as well as in MPA), suggested by the presence of hemosiderin-laden macrophages on BAL. This pattern of frequently recurring DAH is more typical of the ANCA-associated vasculitides and SLE than of nonvasculitic diseases such as rheumatoid arthritis.²³

More than 40 cases of GPA with only DAH and pulmonary capillaritis have been described. Early mortality is 37% and is most often due to acute respiratory or renal failure.^{5,19-21,24,25} Renal disease in the form of a focal segmental necrotizing glomerulonephritis (Fig. 67-7), a cutaneous leukocytoclastic vasculitis, and arthritis often accompany the DAH. Treatment with high-dose corticosteroids and cyclophosphamide has been the recommended initial therapy, which, for DAH of GPA, depending on the severity of the disease, is usually administered intravenously. The role of plasmapheresis is still unclear, but it is often initiated if renal failure is present. Azathioprine may be substituted for cyclophosphamide after remission.²⁶ Recurrences of DAH and other disease manifestation with

tapering of the drug are to be expected. Disease activity can be monitored by the erythrocyte sedimentation rates, ANCA levels, serial DL_{CO} determinations, and microscopic urine examinations. The role of rituximab specifically for the treatment of DAH complicating the vasculitides has not been studied, but it is equal to any other therapy in maintaining remission.²⁷ As previously stated, the differentiation of GPA with DAH from MPA is at times difficult because the clinical presentation, lung histologic features, and serologic findings can be identical.²⁷ In fact, the response to treatment and the tendency for recurrences are similar. The differentiation can be established only after the development of the more typical upper airway disease and pathologic features of GPA.

Microscopic Polyangiitis. MPA has been considered the small vessel variant of polyarteritis nodosa. When present, it is a frequent cause of pulmonary capillaritis and DAH (see eFig. 60-10).^{4,6,21,28-31} MPA is distinguishable from polyarteritis nodosa by the absence of medium-sized blood vessel involvement, the absence of asthma and systemic hypertension, and the relative sparing of the abdominal viscera. DAH has only rarely been documented with polyarteritis nodosa.³²

The most consistent pathologic feature in MPA is a focal segmental necrotizing glomerulonephritis, the renal lesion common to all systemic vasculitides. The lungs are involved by capillaritis in 20% to 30% of cases.³¹ The alveolar hemorrhage tends to be severe and is often life-threatening. Other manifestations include fever, weight loss, cutaneous vasculitis, myalgias, arthralgias, diarrhea, and gastrointestinal bleeding from mucosal vasculitis that is often visible by direct examination, peripheral neuropathy, and in a few cases, sinusitis.^{31,33,34} As with other vasculitides, the erythrocyte sedimentation rate is elevated, and nonspecific increases of serum rheumatoid factor and antinuclear antibody levels are found. Although circulating immune complexes are present in 45% of cases, tissue localization of these complexes is difficult to detect (pauci-immune). Anti-DNA antibodies and hypocomplementemia, findings suggestive of SLE, are absent. A positive serum p-ANCA strongly supports the diagnosis. Antibodies to hepatitis B and C antigens are present in 33% of cases.³⁵

Treatment consists of either oral or intravenous corticosteroids combined with cyclophosphamide or azathioprine.²⁶ Adjuvant treatment with plasmapheresis is recommended by some authors, but its additional efficacy is difficult to determine.³¹ Outcome with early initiation of therapy for MPA is generally good, with a 65% rate of 5-year survival. However, the presence of DAH contributes to an early mortality rate of 25%.^{4,6,21,28-31} There is a tendency for recurrence with tapering of the medications. Factor VIIa has been used successfully with dramatic effects in cases of uncontrolled alveolar hemorrhage.³⁶

The transition to pulmonary fibrosis and restrictive ventilatory impairment after recurrent DAH has been described,¹⁰ and fibrotic lung disease has been reported as the presenting manifestation of MPA.³⁷ There have been three cases of persistent, severe, irreversible airway dysfunction after recurrent episodes of DAH that complicated MPA.³⁸ It is postulated that the combination of recurrent vascular obliteration from capillaritis and the release of

Figure 67-7 Granulomatosis with polyangiitis. Histopathologic findings of a renal biopsy specimen demonstrate focal segmental necrotizing glomerulonephritis. The focal lesion represents an area of fibrinoid necrosis (arrows). (×40 original magnification).

neutral proteases and oxygen radicals from the overwhelming and recurrent burden of neutrophils causes permanent damage to the alveolar septa and results in emphysema.

Isolated Pulmonary Capillaritis. Isolated pulmonary capillaritis is a small vessel vasculitis confined to the lungs and without concomitant systemic involvement.³⁹ There are two forms: one with serum p-ANCA positivity and the other without any positive serologic testing.^{39,40} In one series the latter type was the most frequent cause of pulmonary capillaritis and DAH.³⁹ Direct immunofluorescent studies of the lung in these patients have been negative (pauci-immune). Although respiratory failure necessitating ventilatory support was frequent, response to corticosteroids and cyclophosphamide was good, and only one of eight patients died. Recurrences appeared in two subjects. During a 4-year follow-up period, clinical or serologic evidence for a systemic vasculitis or connective tissue disease did not appear.

Isolated forms of pulmonary capillaritis causing DAH must be distinguished from IPH, which is not associated with pulmonary capillaritis, as well as lung-limited forms of Goodpasture syndrome, the initial presentation of a collagen vascular disease, primary antiphospholipid antibody syndrome, and mitral stenosis. All patients who present with unexplained DAH should have an echocardiogram and undergo surgical lung biopsy.

Mixed Cryoglobulinemia. Mixed cryoglobulinemia is a systemic vasculitis that is recognized by the presence of purpura, arthritis, hepatitis, and glomerulonephritis. It is thought to be an immune complex–induced disease, with most cases linked to hepatitis C (and less commonly hepatitis B) viral infection. Cutaneous vasculitis appearing as raised purpura is the clinical hallmark of this disease. Histologically, there is a perivascular polymorphonuclear infiltration with tissue extravasation and fragmentation in the dermis (leukocytoclastic vasculitis). The renal disease is a proliferative glomerulonephritis with positive granular immunofluorescence. Interstitial lung disease consisting of inflammation and fibrosis of the alveolar walls is the most common pulmonary manifestation.⁴¹ There are two published cases of DAH with pulmonary capillaritis that complicated mixed cryoglobulinemia.^{42,43} rFVIIa failed to control DAH in a patient with cryoglobulinemic vasculitis.^{18a}

Behçet Syndrome. Behçet syndrome is a chronic relapsing illness characterized by oral and genital ulceration, iridocyclitis, thrombophlebitis, and a multisystem disease consisting of a cutaneous vasculitis, arthritis, and meningoencephalitis.⁴³ Immune complexes have been identified in the serum of active cases as well as in the lung and other organs.^{44,45}

The thorax is involved in 5% to 10% of cases of Behçet syndrome. The pulmonary disease is typically a small vessel vasculitis affecting capillaries, venules, and arterioles. The renal disease is a focal segmental necrotizing vasculitis, as is seen in other systemic vasculitides. Immune complexes composed of IgG and complement have been identified in small pulmonary vessels in several cases.^{44,45} In addition to alveolar hemorrhage, involvement of larger vessels can lead to aneurysms of the pulmonary (eFig. 67-2) and bronchial

arteries, the latter potentially eroding into bronchi, causing massive pulmonary hemorrhage and death.^{46,47} Another potential cause for pulmonary hemorrhage in Behçet syndrome is pulmonary arterial occlusion with infarction.⁴⁵ A review of 28 cases of pulmonary involvement in Behçet syndrome emphasized several points: pulmonary complaints consisting of cough, hemoptysis, chest pain, and fever were more common in men than in women; 39% of patients died of pulmonary hemorrhage, usually within 6 years of the first episode of hemoptysis.⁴⁸ Other studies have confirmed the seriousness of this complication regardless of its cause.^{46,47} Treatment consists of corticosteroids and immunosuppressive therapy.⁴⁹ Treatment with anti-tumor necrosis factor therapy has shown dramatic results in case reports.⁵⁰

Henoch-Schönlein Purpura. Henoch-Schönlein purpura, primarily a disease of children, also can be seen in adults.⁵¹ Adults typically present with palpable purpura (leukocytoclastic vasculitis) and glomerulonephritis.¹⁶ The joints and gastrointestinal tract are commonly involved. Pulmonary involvement is unusual. In several large series, pulmonary disease, except for transient chest radiographic opacities, was not mentioned.¹⁶ There have been documented cases of DAH with pulmonary capillaritis in patients with Henoch-Schönlein purpura.^{52,53} In one, IgA immune complexes were present in the alveolar septa.⁵² It is postulated that IgA immune complexes, which are present in the serum and kidneys of these patients, are responsible for the tissue damage that results in the clinical syndrome.⁵⁴ Corticosteroids were used in both cases and are generally recommended.

Pauci-immune Glomerulonephritis. Pauci-immune glomerulonephritis is one of three types of isolated renal vasculitides (the other two being immune complex–mediated glomerulonephritis and Goodpasture syndrome). Pauci-immune glomerulonephritis lacks any immunoreaction product except for minimal accumulation of fibrin. It is histologically and immunologically similar to the glomerulonephritis of MPA and GPA and is considered to represent a form of renal-limited vasculitis.²¹ Up to 50% of affected patients develop pulmonary capillaritis and DAH, and a smaller number develop a full-blown systemic vasculitis indistinguishable from MPA. Another indication that pauci-immune glomerulonephritis represents a limited form of vasculitis is the presence of serum p-ANCA in these patients. Because clinical manifestations are often limited to the lung and kidney, it can be confused with Goodpasture syndrome.^{21,54} Pauci-immune glomerulonephritis is distinguished by the absence of circulating basement membrane antibodies in the serum and by the negative findings on renal immunofluorescence studies. Treatment with high-dose corticosteroids plus immunosuppressive therapy with either cyclophosphamide or azathioprine is recommended.

Immunologic

Goodpasture Syndrome. Whether the case reported by Goodpasture in 1919⁵⁵ describes the syndrome that bears his name is questionable. He described an 18-year-old man who died 6 weeks after an influenza infection and was

found to have DAH, pleuritis, glomerulonephritis, splenic infarctions, and vasculitis of the small intestines. In 1965 an *anti-glomerular basement membrane antibody* (ABMA)—now identified as an antibody against the NC1 domain of the $\alpha 3$ chain of type IV collagen—was identified in the kidneys and lungs of some patients with DAH and glomerulonephritis.^{56,57} The diagnosis of Goodpasture syndrome, also known as *ABMA disease*, is reserved for cases of DAH and glomerulonephritis in which this antibody appears in the serum, is bound to kidney and/or lung basement membranes in a linear manner by immunohistochemistry, or both.²¹

At least 90% of patients with Goodpasture syndrome have circulating ABMA.⁵⁸ The level of ABMA is not generally considered an accurate index of disease activity, although higher levels have been associated with more severe renal disease. In 60% to 80% of cases, the lung and renal disease appear simultaneously; in 5% to 10%, only the lung is affected; and in the remainder, renal disease exists by itself.^{59,60} It is clear that ABMA is pathogenetic; however, the stimulus for its production remains unknown. The clinical onset of Goodpasture syndrome has been temporarily related to infection with influenza A2 as well as to other respiratory infections, hydrocarbon exposure, and tobacco use.^{61–63} The presence of histocompatibility *human leukocyte antigen* (HLA)-DRw2 and HLA-B7 (90% and 60%, respectively) in patients with Goodpasture syndrome indicates that susceptible individuals are predisposed to disease that is often severe and progressive.^{64,65} It is interesting to note that, in some experimental models, the introduction of ABMA produces renal but not pulmonary disease; for the antibody to deposit in the lung, an additional injury is required that increases alveolar-capillary permeability.^{66,67}

Men are more commonly affected (60% to 80% of patients), and the concentration of cases is greatest between the ages of 20 and 30 years.^{68,69} In older cases, the sex distribution is equal and the disease tends to be limited to the kidney.⁶² Interestingly, DAH is more common in patients who smoke.⁶² The alveolar permeability is increased in most smokers, and this is thought to be an important factor leading to DAH.⁶¹ In one study, 100% of smokers with Goodpasture syndrome developed both DAH and glomerulonephritis, whereas only 20% of nonsmokers developed DAH.⁶² Resumption of cigarette smoking by patients who are in remission can result in recurrent episodes of DAH. Exposure to volatile hydrocarbons (e.g., petroleum products, turpentine, toluene, and pesticides) is associated with initiation, as well as exacerbations, of DAH.^{59,60,70,71}

Symptoms most often refer to the lungs and consist of hemoptysis, cough, and dyspnea. Fatigue caused by iron-deficiency anemia and renal failure may predominate. Microscopic hematuria, proteinuria, and increases in the serum creatinine level are often present, but gross hematuria with hypertension is unusual. The diffusing capacity may be increased during periods of active bleeding and is considered to be a useful monitor of new or recurrent DAH.⁷² An increase of 30% above baseline is highly suggestive of an intra-alveolar hemorrhage, and this increase may precede pulmonary symptoms or radiographic changes. Chest radiography often reveals patchy air space abnormalities (eFig. 67-3A and B). HRCT scanning (see eFig. 67-3C) typically shows ground-glass opacities and

Figure 67-8 Goodpasture syndrome (ABMA disease). Immunofluorescence study demonstrates linear staining of immunoglobulin G in the alveolar walls in a patient with Goodpasture syndrome (ABMA disease) ($\times 10$ original magnification).

consolidation and is more sensitive for DAH than is chest radiography.⁷³

Pulmonary capillaritis is present in some cases of Goodpasture syndrome, but the usual histologic appearance is bland pulmonary hemorrhage.⁷¹ Alveolar wall necrosis, which is seen with systemic vasculitis, is not a feature of Goodpasture syndrome. The renal histologic findings are a focal segmental necrotizing glomerulonephritis with crescent formation. The major distinction between Goodpasture syndrome and the other rapidly progressive glomerulonephritides is the presence of an uninterrupted linear deposition of immunoglobulin and complement along the glomerular basement membrane (Fig. 67-8). Identical findings are present on alveolar basement membranes.⁷⁴ Even when DAH dominates the clinical picture (i.e., there is no evidence of renal disease), renal biopsy will still reveal the typical linear staining.⁷⁵

In the minority of patients without clinically evident renal involvement, DAH responds to oral or intravenous corticosteroids. Glomerulonephritis, if present, appears resistant to corticosteroid monotherapy. The combination of plasmapheresis (3 to 6 L daily for 2 weeks), corticosteroids, and cytotoxic drugs is effective, particularly in patients who do not have oligoanuria and do not require dialysis.^{76–80} The combination of cyclophosphamide or azathioprine with corticosteroids leads to a dramatic fall in circulating ABMA, and oliguric dialysis-dependent subjects have responded to the point at which dialysis could be discontinued.^{80,81} Anuric patients do not respond well to this combination therapy, and dialysis and renal transplantation are often necessary.⁸¹ Case reports of successful treatment of refractory, life-threatening Goodpasture syndrome with mycophenolate mofetil and anti-CD20 monoclonal antibody have been reported.^{82,83} Bilateral nephrectomy no longer has a role in the management of Goodpasture syndrome.

Over time, the survival rate in Goodpasture syndrome has improved from 80% mortality at 6 months (half dying from DAH and the rest from renal insufficiency) to approximately 50% at 2 years.⁶⁹ With the aggressive treatment approach described previously, it is estimated that the

5-year survival rate exceeds 80%, and fewer than 30% of patients require long-term dialysis. DAH is the usual cause of death, often being precipitated by a concomitant infection.⁶⁰ There has been spontaneous remission in cases without clinical evidence of renal disease, although this is not usual.⁸⁴ The most useful prognostic information comes from the kidney. Clinically, oliguric or anuric renal failure reduces the survival rate to 50% at 6 months. Histopathologically, less than 30% involvement of the glomeruli on biopsy predicts significant therapeutic response and improved survival. When 70% or more of glomeruli have formed crescents in conjunction with renal insufficiency, renal failure is progressive and often unresponsive to therapy, eventually necessitating dialysis.⁸¹

Connective Tissue Disease. Among the connective tissue diseases, DAH is most commonly seen in SLE (eFig. 67-4).^{21,85-87} It is unusual for DAH to be the initial manifestation of SLE, in contrast to acute lupus pneumonitis, which is often the initial manifestation.^{88,89} Most patients with DAH have active lupus nephritis.⁸⁶ The onset of alveolar hemorrhage can be dramatic, producing severe gas-exchange abnormalities and necessitating mechanical ventilation. Reduced complement levels and increased serum titers of serum antinuclear antibodies confirm the diagnosis.

DAH must be distinguished from other causes of hemoptysis in SLE, specifically acute lupus pneumonitis. Acute lupus pneumonitis presents with fever, cough, and dyspnea. In 50% of cases, this is the initial manifestation of SLE.⁸⁹ It is an inflammatory condition, characterized histologically by organizing pneumonia, DAD, cellular nonspecific interstitial pneumonia, and occasionally, intra-alveolar hemorrhage. Although hemoptysis may accompany acute lupus pneumonitis, significant reductions of the hemoglobin level are not to be expected. Unlike DAH, pleural and pericardial effusions are common in acute lupus pneumonitis. Other diagnostic considerations in the patient with suspected DAH include infectious pneumonias and pulmonary infarction associated with deep venous thrombosis with or without a circulating lupus anticoagulant.^{90,91}

Histopathologic examination of DAH in patients with SLE generally reveals capillaritis, but bland pulmonary hemorrhage and DAD have been described.^{89,92} Granular deposits of IgG and complement (C3) are commonly found in the alveolar interstitium and within the walls of intra-alveolar blood vessels (Fig. 67-9).^{85,92-94} Capillaritis and immune complex deposition do not necessarily overlap. In one series of four patients with SLE and massive DAH associated with pulmonary capillaritis, only two demonstrated immune complexes by light and electron microscopic techniques.⁹⁵

Treatment of DAH caused by SLE includes high-dose intravenous corticosteroids as well as azathioprine or cyclophosphamide. rFVIIa administered via local intrapulmonary route may be an effective treatment option for DAH in SLE patients.^{18b} Plasmapheresis has been combined with chemotherapy in some cases, but its utility is unknown.⁸⁶ Broad-spectrum antibiotic coverage is recommended because of some evidence that infection may trigger the hemorrhage.⁸⁶ DAH is associated with a 50% mortality rate in SLE and can be recurrent in survivors.^{88,92-96} Death is caused by massive hemorrhage, concurrent infection, or renal or central nervous system disease.

Figure 67-9 Systemic lupus erythematosus. Immunofluorescence study demonstrates granular deposition of immunoglobulin G in the alveolar walls of a patient with systemic lupus erythematosus and diffuse alveolar hemorrhage ($\times 40$ original magnification).

Rarely, DAH and glomerulonephritis develop in patients with rheumatoid arthritis,⁹⁷ scleroderma,⁹⁸ or mixed connective tissue disease. Isolated DAH with capillaritis has also been described in polymyositis, rheumatoid arthritis, and mixed connective tissue disease.^{99,100} In polymyositis, DAH was the presenting manifestation, and in rheumatoid arthritis and mixed connective tissue disease, DAH and capillaritis followed the primary diagnosis (2 to 20 years).^{99,100} The absence of a systemic vasculitis in these cases, including glomerulonephritis, was unexpected.

Immune Complex–Related Crescentic Glomerulonephritis. Immune complex–related crescentic glomerulonephritis is rarely accompanied by capillaritis and DAH.^{1,101} Although the kidneys demonstrate granular immune deposits, immune complexes are not found in lung tissue.

Acute Pulmonary Allograft Rejection. Pulmonary capillaritis and DAH have been reported after lung transplantation for a variety of underlying diseases.¹⁰² The suspected acute vascular rejection can develop weeks to months after the transplantation and may be the only histopathologic manifestation of allograft rejection. This represents a serious immunologic complication that threatens survival. In addition to standard anti-inflammatory therapy with corticosteroids and cytotoxic agents, plasmapheresis may be effective.

Coagulation Disorders

Coagulation disorders associated with DAH include disseminated intravascular coagulation,¹⁰³ idiopathic thrombocytopenic purpura,¹⁰⁴ thrombotic thrombocytopenic purpura,¹⁰⁵ acquired vitamin K deficiency,¹⁰⁶ and antiphospholipid antibody syndrome.¹⁰⁷ Uniquely among coagulation disorders, primary antiphospholipid antibody syndrome–associated DAH is often associated with capillaritis (eFig. 67-5).¹⁰⁸

All anticoagulant medications have been associated with DAH, including warfarin (Coumadin) and its derivatives,¹⁰⁹⁻¹¹¹ thrombolytics,^{112,113} agents targeting the platelet glycoprotein IIb/IIIa,¹¹⁴⁻¹¹⁶ and clopidogrel.¹¹⁷ In most

iatrogenically anticoagulated patients, correction of the coagulation defect resolves the DAH. It has been suggested that patients using coumarins with confirmed DAH are at risk for the development of fibrosing interstitial pneumonitis.¹¹⁸

DAH is common in patients with acute leukemia who have undergone induction chemotherapy and are thrombocytopenic (eFig. 67-6).¹¹⁹⁻¹²¹ Although thrombocytopenia surely contributes to the DAH, these patients also have evidence of DAD due to chemotherapy, oxygen toxicity, and infection that likely plays a central role.

Idiopathic Pulmonary Hemosiderosis

IPH is predominantly a disease of children, but adults represent about 20% of cases.^{120,121} It is a diagnosis of exclusion,^{122,123} and efforts to rule out other causes of DAH are essential. Among adults, men are more often affected, and there are reports of familial cases.¹²⁴ Some cases have been described in the setting of celiac disease, and serum IgA levels are increased in 50% of cases.^{125,126} The pathogenesis of IPH is not understood. Some cases may be secondary to environmental exposures, such as *Stachybotrys atra*, a toxigenic fungus that has been potentially linked to several cases of otherwise idiopathic alveolar hemorrhage.¹²⁷

Recurrent hemoptysis due to DAH is the rule, ranging from intermittent blood-streaked sputum to life-threatening hemorrhage. Fever, cough, substernal chest pain, and fatigue secondary to iron-deficiency anemia are also reported. In selected pediatric cases, lymphadenopathy and hepatosplenomegaly are found. Renal disease is absent. In chronic recurrent disease, progressive dyspnea, finger clubbing, inspiratory crackles, and pulmonary fibrosis appear. Pulmonary function testing reveals a restrictive ventilatory defect with an increase in the DL_{CO} during periods of active bleeding. Chest imaging reveals diffuse ground-glass opacity (eFigs. 67-7 and 67-8) and ill-defined centrilobular nodules, the typical appearance of pulmonary hemorrhage of any cause.¹²⁸ Measurements of serum antibodies reveal the absence of alternative causes.

In adult cases, lung tissue is required to exclude the entity of isolated pulmonary capillaritis. The histologic examination of the lung in IPH reveals bland alveolar hemorrhage with hemosiderin accumulation.^{123,129} There is hyperplasia of type II alveolar epithelial cells with capillary dilation and tortuosity. The iron content of the lung is increased, and it is the hemosiderin deposition in the interstitium that is thought to be the basis for collagen proliferation and parenchymal fibrosis. Pulmonary immune complexes are absent, differentiating IPH from isolated pulmonary Goodpasture syndrome. Electron microscopic studies indicate degeneration of type I alveolar epithelial cells with exposure of and breaks in the basement membrane and discontinuity of the alveolar capillary structure.^{127,128} Although nonspecific, these findings indicate a form of DAD.

Clinical benefit and recovery from the acute hemorrhage after corticosteroid therapy have been reported, but long-term benefit is unlikely.^{123,130} Azathioprine has been successful in several cases.^{129,131,132} Approximately 25% of patients are free of disease after the initial episode. Another 25% are free of active disease but have persistent dyspnea and anemia, and another quarter have persistent active disease that leads to fibrosis and severe restrictive lung

disease. The rest have unresponsive disease with continued hemorrhage and death from respiratory failure. In those with persistent disease, the average survival is 3 to 5 years.^{123,130} Adults have a better prognosis than children. Lung transplantation is controversial in this disease because IPH has been reported to recur after bilateral lung transplantation.¹³³

Other Causes of Diffuse Alveolar Hemorrhage

Drugs/Toxins. There are many drugs that have been reported to cause DAH.^{133a} Anticoagulants have been discussed previously. Most DAH due to drugs or toxins is associated with DAD. This has been reported with abciximab, amiodarone, azathioprine, carbamazepine, cyclosporine, ara-C, dextran, docetaxel, fludarabine, hydralazine, methotrexate, radiographic contrast media, retinoic acid, sirolimus, tumor necrosis factor- α , and valproate.¹³⁴

A few drugs have been associated with DAH and capillaritis, including tretinoin, propylthiouracil, phenytoin, and mitomycin.¹³⁵⁻¹³⁹ DAH due to these drugs may also be associated with crescentic glomerulonephritis and elevated ANCA levels.

Penicillamine can result in DAH and an immune complex-mediated glomerulonephritis. Glomerular capillaries display a granular (as opposed to a linear) immunofluorescent pattern for IgG and C3.¹⁴⁰⁻¹⁴² Cases have appeared after as much as 20 years of treatment. Some authors have called this a drug-induced Goodpasture syndrome, but the pattern of immunoglobulin deposition in the kidney differentiates this entity. Treatment with immunosuppressive therapy and even plasmapheresis may be required.¹⁴³

Trimellitic anhydride is used for the manufacture of paints, epoxy resins, and plastics. DAH has been reported after the inhalation of fumes or dry powder, generally during spraying of this product on heated surfaces.¹⁴⁴⁻¹⁴⁶ Antibodies to trimellitic anhydride in the serum and a latent period of 1 to 3 months both support an immunologic basis for this syndrome. Long-term physiologic impairment is unusual if further exposure is avoided.

Diffuse Alveolar Damage. DAD is the underlying histopathologic feature of acute lung injury, and it has a variety of causes (Table 67-3). In DAD the interstitium of the lung becomes edematous, and the type I alveolar epithelial lining cells are sloughed. There is neutrophilic inflammation and fibroblastic proliferation. Hyaline membranes (eosinophilic strands of necrotic cells, protein, and fibrin) develop adjacent to the injured alveolar walls. In severe cases, red blood cells may enter the alveolar space as a result of injury to the alveolar-capillary interface, resulting in DAH. The neutrophilic inflammation in DAD-associated DAH is not as intense as it is in pulmonary capillaritis.

Mitral Stenosis. Mitral stenosis can be clinically silent and, over time, can result in substantial pulmonary venous hypertension. In some cases this can lead to the development of DAH.¹⁴⁷ The presentation can be dramatic, with massive hemoptysis arising from the rupture of engorged bronchial varicosities that develop as a result of long-standing left atrial hypertension. Less severe DAH may be recurrent and is often misdiagnosed, leading to chronic

interstitial fibrosis. Radiographic findings consist of central ground-glass abnormalities and, in chronic cases, reticular abnormalities (eFig. 67-9).¹⁴⁸ Repair or replacement of the stenotic mitral valve prevents recurrence.

Pulmonary Veno-occlusive Disease. *Pulmonary veno-occlusive disease* (PVOD) is a rare cause of pulmonary hypertension due to fibrous obliteration of small pulmonary veins and venules. PVOD affects men and women equally and involves all age-groups, most commonly children and young adults.¹⁴⁹⁻¹⁵¹ Patients with PVOD present with dyspnea, syncope, and, when severe, physical findings suggestive of cor pulmonale. Because PVOD is a postcapillary cause of pulmonary hypertension, paroxysmal nocturnal dyspnea, orthopnea, and DAH can be seen.

Right heart catheterization cannot easily distinguish PVOD from precapillary pulmonary hypertension because the pulmonary capillary wedge pressure is generally normal. Imaging shows signs of pulmonary hypertension; in some cases, interstitial opacities with septal thickening (see Fig. 58-3) suggesting congestion as well as ground-glass abnormality from alveolar hemorrhage may be seen. Pleural effusions are common.

Pulmonary function studies reveal a reduced DL_{CO} with preservation of lung volumes, a physiologic picture similar to that found in other causes of pulmonary hypertension. Definitive diagnosis is achieved by lung biopsy, which demonstrates fibrous intimal obliteration of small pulmonary veins and venules, acute or recanalized thrombi, and hemosiderosis (Fig. 67-10).

Most cases of PVOD are idiopathic, but it has been reported after chemotherapy (e.g., carmustine, mitomycin, bleomycin) for malignant disease, bone marrow transplantation, and associated with connective tissue disease.¹⁵²⁻¹⁵⁹ A mutation in the *bone morphogenetic protein receptor II gene* (BMP2), a gene associated with many cases of primary pulmonary hypertension, has been identified in a patient with idiopathic PVOD, suggesting a potential etiologic role.¹⁶⁰

The use of pulmonary vasodilators in the treatment of PVOD is complicated and potentially harmful. Modest improvements with nifedipine and epoprostenol have been

Figure 67-10 Histopathologic findings of pulmonary veno-occlusive disease. An elastic tissue stain (elastic van Gieson) shows marked intimal sclerosis with venous narrowing. These cases may show mild interstitial chronic inflammation and air space accumulation of hemosiderin-filled macrophages (hemosiderosis). (Courtesy Dr. Kirk Jones, University of California, San Francisco.)

reported, but there have also been cases of these agents precipitating massive pulmonary edema and death.^{161,162} Any trial of vasodilator therapy should be performed during right heart catheterization in an appropriate hospital setting. A few patients have had clinical responses to prednisone and azathioprine.^{163,164} Anticoagulation for PVOD has been recommended based on the potential role of thrombosis in the pathogenesis of PVOD and on limited data suggesting efficacy in patients with primary pulmonary hypertension. Anticoagulants should generally be avoided in patients who have had DAH.

Pulmonary Capillary Hemangiomatosis. Pulmonary capillary hemangiomatosis is a rare cause of pulmonary hypertension that can be associated with severe and recurrent DAH.¹⁶⁵⁻¹⁶⁷ It is seen across age and gender. Patients universally present with dyspnea, often with evidence of right heart failure. Hemoptysis develops in roughly one third of cases during the course of the disease.¹⁶⁵ Imaging findings are nonspecific, with chest radiography often showing nonspecific diffuse or bibasilar predominant reticular (eFig. 67-10A) and nodular opacities, with interlobular septal thickening less common than seen with PVOD. Chest *computed tomography* (CT) may show multifocal or diffuse, poorly defined centrilobular ground-glass opacity nodules (eFig. 67-11; see eFig. 67-10B) and evidence of pulmonary arterial hypertension. Pulmonary function test results are mixed, with both obstructive and restrictive changes described.¹⁶⁵ As with PVOD, right heart catheterization generally reveals a normal pulmonary capillary wedge pressure.

Pulmonary capillary hemangiomatosis is characterized by a proliferation of pulmonary capillaries, which infiltrate the interstitial, bronchial, and vascular structures of the lung (Fig. 67-11).¹⁶⁶ The exact mechanism of pulmonary hypertension and DAH is unclear, but mechanical rupture of hemangiomatous vessels in the setting of pulmonary arterial and venous occlusion and/or thrombosis is likely responsible. Treatment of pulmonary capillary hemangiomatosis with pulmonary vasodilators is generally

Figure 67-11 Histopathologic findings of pulmonary capillary hemangiomatosis. There is capillary proliferation in the wall of this large pulmonary vein (×100 original magnification).

contraindicated because worsening pulmonary edema and death have been reported as a result.^{168,169} In a few reports, treatment with recombinant interferon-alfa-2a may have led to stabilization or improvement.^{165,170} Mean survival after diagnosis is usually 3 years, although successful treatment with lung transplantation has been reported.¹⁶⁵

Lymphangioleiomyomatosis and Tuberous Sclerosis. Lymphangioleiomyomatosis and tuberous sclerosis share a common pathobiology involving proliferation of smooth muscle in pulmonary interstitial, lymphatic, bronchial, and vascular structures (see Chapter 69 for a full discussion of these diseases).¹⁷¹⁻¹⁷³ Involvement of the pulmonary vasculature commonly results in episodes of alveolar hemorrhage. This alveolar bleeding is often focal; DAH is unusual. Pathologic specimens of the lung in lymphangioleiomyomatosis and tuberous sclerosis typically demonstrate focal areas of hemorrhage and hemosiderin deposition.

RARE INFILTRATIVE DISORDERS OF THE LUNG

NEUROFIBROMATOSIS

There are two clinically and genetically distinct forms of neurofibromatosis termed “neurofibromatosis 1” and “neurofibromatosis 2.” Lung disease is generally associated with neurofibromatosis 1, also known as von Recklinghausen disease.¹⁷⁴ Neurofibromatosis 1 is an autosomal dominant disease caused by mutations in the *NF1* gene at 17q11 and is characterized clinically by the appearance of cutaneous café au lait spots, subcutaneous neurofibromas, and Lisch nodule in the iris. The thoracic manifestations of neurofibromatosis are listed in Table 67-4. Interstitial lung disease arises in 10% to 20% of affected patients, with dyspnea appearing between the third and the sixth decades.¹⁷⁵⁻¹⁷⁹ Lower zone interstitial disease is the rule, with bullous disease eventually appearing in the upper zones.¹⁸⁰ Physiologic testing early in the course of the disease reveals restrictive ventilatory impairment, but with time, an obstructive lung disease supervenes, because the fibrotic

Kyphoscoliosis
Apical neurofibroma (Pancoast syndrome)

process in the lung involves not only the interstitium but also the small airways. Histopathologic examination reveals cellular and fibrotic interstitial pneumonia.¹⁷⁵ Scar carcinoma has been reported as a complication of neurofibromatosis.¹⁷⁸

HERMANSKY-PUDLAK SYNDROME

Hermansky-Pudlak syndrome is an autosomal recessive disorder characterized by oculocutaneous albinism and bleeding, found predominantly in inhabitants of Puerto Rico and southern Holland.¹⁸¹⁻¹⁸³ The biochemical defect is unknown, although putatively responsible genes have been identified and several mutations have been reported.¹⁸⁴ In patients with this disease, there is an accumulation of a chromolipid ceroid (related to lipofuscin) in the reticuloendothelial system. This results in partial tyrosine-negative albinism and a qualitative platelet defect. In addition, granulomatous colitis and progressive pulmonary fibrosis develop.

The interstitial lung disease is more common in women and develops during the second through fourth decades.¹⁸² It progresses slowly and is unresponsive to treatment. Spirometry and measurement of lung volumes reveal restrictive lung disease. Chest radiography shows reticular opacities that progress to radiographic honeycombing over time. The histologic appearance is one of extensive interstitial fibrosis with filling of the alveolar spaces by ceroid-containing macrophages. These macrophages are identified in BAL and by subsequent staining with the Fontana-Masson silver reduction technique. No effective medical treatment of the interstitial lung disease has been reported.¹⁸⁵

DYSKERATOSIS CONGENITA

Dyskeratosis congenita (DKC) is a rare inherited condition consisting most generally of mucocutaneous features, including nail dystrophy, skin pigmentation, and oral leukoplakia.^{186,187} Mutations in the genes encoding telomerase and telomere maintenance have been identified in nearly 50% of patients with this disease. Most patients with DKC are male, suggesting an X-linked pattern of inheritance.¹⁸⁸ Telomere length is important to control of cell division, and shortening of telomeres (either due to aging or inherited abnormalities) eventually leads to cellular senescence. In

DKC this most commonly manifests as bone marrow failure (isolated cytopenias to aplastic anemia).

Pulmonary fibrosis has been described in patients with DKC.¹⁸⁹ This was initially described in patients following bone marrow transplant and may have been the result of increased susceptibility to chemotherapy-related pulmonary toxicity.¹⁹⁰ Since that time, additional cases of pulmonary fibrosis in patients with DKC have been reported.¹⁹¹ There is little information on the histopathologic appearance of these cases. Approximately 11% of deaths in one cohort were due to pulmonary complications, with another 11% of deaths due to pulmonary complications of bone marrow transplantation.¹⁹¹

GAUCHER DISEASE

Gaucher disease results from a deficiency in the enzyme glucocerebrosidase, a central component of ganglioside catabolism. The infantile form of Gaucher disease, a hereditary disorder that is most common in Ashkenazi Jewish persons, is uniformly fatal because of central nervous system involvement. However, the adult form (type 1 disease) is relatively benign and is associated with good long-term survival. This condition presents with hepatosplenomegaly, anemia, thrombocytopenia, long-bone erosions, and an increase in serum acid phosphatase level. It is an autosomal recessive disease, the pathologic hallmark being the Gaucher cell. The Gaucher cell is a reticuloendothelial cell with a foamy cytoplasm due to the accumulation of glucocerebrosides. This leads to an excessive deposition of glucocerebrosides in the reticuloendothelial system, bone marrow, central nervous system, and occasionally the lung.

Pulmonary disease develops in only a small minority of adult cases.¹⁹²⁻¹⁹⁴ Parenchymal disease, which consists of radiographically visible small nodules, appears during the first 3 decades of life. Pathologic examination reveals conglomerate masses of glucocerebroside-filled macrophages in the alveolar spaces and infiltrating the interstitium. Remarkably, there is limited to no acute or chronic inflammation or fibrosis. In addition to interstitial lung disease, affected patients are susceptible to lung infection. A single case of pulmonary hypertension from diffuse small vessel obstruction by these cells has been reported.¹⁹⁵ Although enzyme replacement (glucocerebrosidase) has therapeutic promise for many of the manifestations of Gaucher disease, the interstitial lung disease appears unresponsive.¹⁹⁶

NIEMANN-PICK DISEASE

Niemann-Pick disease results from a deficiency of sphingomyelinase that causes accumulation of sphingomyelin in the cells of the reticuloendothelial and central nervous systems.¹⁹⁷ As in Gaucher disease, there is an infantile form of Niemann-Pick disease that is rapidly fatal. The adult form (type B disease), which appears during the second and third decades, is relatively benign, presenting with hepatosplenomegaly, hemostatic defects, platelet dysfunction, and occasionally, cerebellar ataxia. Interstitial lung disease, which appears as diffuse nodular opacities on imaging (eFig. 67-12), is usually asymptomatic, although a mild restrictive ventilatory defect and reduced diffusing capacity

Figure 67-12 Histopathologic findings of pulmonary alveolar microlithiasis. Alveolar spaces are filled by lamellated, rounded microliths. (Courtesy Dr. Kirk Jones, University of California, San Francisco.)

have been reported.^{198,199} As in Gaucher disease, collections of foamy alveolar macrophages are found on lung biopsy. Bronchial casts can be observed as a feature of Niemann-Pick disease, and extraction of bronchial casts and whole-lung lavage may facilitate clinical and radiologic improvement in such patients.²⁰⁰

PULMONARY ALVEOLAR MICROLITHIASIS

Pulmonary alveolar microlithiasis is an idiopathic rare disease in which concretions composed of calcium and phosphorus collect in alveolar spaces (Fig. 67-12).^{201,202} In more than 50% of cases, a familial association is found.²⁰³ A systemic disorder of calcium metabolism has not been identified, and the serum calcium and phosphate levels are normal. Most authors believe that the responsible mechanism is an inborn error of calcium metabolism that is confined to the lung and leads to precipitation of the salts.

Most cases of pulmonary alveolar microlithiasis are diagnosed during the third through fifth decades. Among familial cases, women are affected more often than men, but there is an equal distribution among the sporadic cases.^{203,204} Cough and dyspnea are the most common presenting symptoms. Expectorated microliths have been reported.²⁰¹ Inspiratory crackles, finger clubbing, and signs of cor pulmonale may be present in more advanced disease.

The chest radiograph is characteristic and shows diffuse bilateral calcific opacities with predilection for the lower lung zone (eFig. 67-13A). This opacity is alveolar, producing air bronchograms and radiographic obliteration of the heart borders, pulmonary vessels, and diaphragmatic surfaces.²⁰⁵ Chest CT (see eFig. 67-13B-I; Video 67-1) often demonstrates widespread intra-alveolar calcified nodules with a lower lobe and subpleural predominance, although early disease can be less conspicuous (Fig. 67-13).^{206,207} Pulmonary function remains normal or only slightly impaired for a prolonged period after disease detection.²⁰⁸ With time, the alveolar walls become fibrotic, and a restrictive ventilatory defect with a reduced DL_{CO} develops. Technetium-99m bone scintigraphy or transbronchial lung biopsy can provide confirmation of the diagnosis.^{209,210} Treatment is supportive. Whole-lung lavage has been tried without benefit.²¹¹

Figure 67-13 Pulmonary alveolar microlithiasis. Chest radiograph showing the widespread intraalveolar deposition of calcium-containing microliths, with a lower lobe predominance.

Key Points

- *Diffuse alveolar hemorrhage* (DAH) is a medical emergency that often results in acute respiratory failure and death.
- The classic clinical presentation of DAH includes hemoptysis, alveolar opacities on chest radiograph, and anemia.
- Many of the disorders causing DAH appear to be immunologically mediated, either through injury to the capillary basement membrane by specific autoantibody or through deposition of immune complexes.

- Bronchoscopy with serial bronchoalveolar lavage is essential to the accurate identification of DAH.
- Many cases of DAH demonstrate neutrophilic inflammation of the alveolar interstitium known as capillaritis.
- The presence of proteinuria and an abnormal urinary sediment (red blood cells and red blood cell casts) suggests an underlying glomerulonephritis consistent with the diagnosis of systemic vasculitis or Goodpasture syndrome (anti-glomerular basement membrane antibody disease).
- Accurate diagnosis is essential because aggressive treatment with corticosteroids, cytotoxic agents, rituximab, and plasmapheresis (alone or in combination) is often helpful.

INTRODUCTION

The eosinophilic lung diseases are a group of disorders (Table 68-1) characterized by the presence and presumed pathogenetic role of eosinophils in the disease processes. They are mainly represented by the eosinophilic pneumonias, which are defined by a prominent infiltration of the lung parenchyma by eosinophils. The other eosinophilic lung diseases mainly involve the airways, as in the allergic bronchopulmonary mycoses and hypereosinophilic obliterative bronchiolitis. Asthma, in which the eosinophil plays an important role, is not discussed in this chapter.

EOSINOPHIL BIOLOGY

The role of the eosinophil in homeostasis function, physiology, and pathophysiology has become better appreciated in recent years.¹⁻³ Eosinophils are multifunctional leukocytes implicated in innate and adaptive immunity, including numerous inflammatory reactions to parasitic helminth, bacterial, and viral infections.³ They have been especially credited with a beneficial role in parasitic infestation; however, results from in vivo infection studies have given conflicting results.⁴

The eosinophil^{1-3,5} matures in the bone marrow under the action of cytokines and especially of *interleukin* (IL)-5 (involved in the differentiation of eosinophil precursors), IL-3, and *granulocyte-macrophage colony-stimulating factor* (GM-CSF) and the activation of transcription factors including *Adbl-GATA-1*. The eosinophil then circulates in the blood for about 1 day before being attracted into tissues by complex processes including adhesion and attraction, diapedesis, and chemotaxis, where it undergoes apoptosis unless survival factors are present.

Major advances have been made in the understanding of molecular and intracellular pathways regulating eosinophil

differentiation, priming, activation, degranulation, and mediator secretion (with especially the role of vesicle-associated membrane proteins in the regulation of granule fusion in eosinophils).⁵ The eosinophil contains two types of intracytoplasmic granules. The larger granules, characterized by an electron-dense crystalloid matrix, contain the characteristic cationic proteins, which have direct toxicity to the heart, brain, and bronchial epithelium. The smaller amorphous granules contain arylsulfatase and acid phosphatase. Activation of the eosinophil results in degranulation with the extracellular release of the eosinophil-specific proteins, including *major basic protein* (MBP), eosinophil cationic protein, eosinophil-derived neurotoxin, and the enzymatic protein *eosinophil peroxidase* (EPO). The finding of vacuoles in the cytoplasm of the eosinophil and ultrastructural evidence of loss of electron density from the central core of the granules (inversion or disappearance of core density) morphologically characterizes the process of degranulation. Eosinophils also release proinflammatory cytokines, arachidonic acid-derived mediators, enzymes, reactive oxygen species, and matrix metalloproteases. They express a variety of surface proteins, including adhesion molecules, apoptotic signaling molecules, chemokines, complement receptors, chemotactic factor receptors, cytokine receptors, and immunoglobulin receptors. The release of toxic substances in itself contributes to the pathophysiology of eosinophilic disorders.

Many biologic properties of the eosinophil are directed by *T helper* (Th) lymphocytes, but the eosinophil interacts in many allergic or inflammatory processes with other cells including mast cells and basophils, endothelial cells, macrophages, platelets, and fibroblasts. Eosinophils are capable of regulating mast cell function and histamine release. Activated eosinophils express the major histocompatibility complex II protein *human leukocyte antigen*, (HLA)-DR, and possess the ability to participate in numerous immune functions, including antigen presentation and secretion of an

array of cytokines capable of promoting effector T-cell proliferation. In addition, eosinophils are implicated in the regulation of Th1/Th2 balance, through synthesis of IL-4, promotion of IL-4, IL-5, and IL-13 secretion by CD4⁺T cells, as well as the synthesis of indoleamine 2,3-dioxygenase (indirectly promoting Th1 apoptosis). Identification of the immune and multifunction properties of the eosinophil has changed the view on eosinophils, from a terminal effector cell in allergic airway diseases to the current paradigm of eosinophils being involved in the initial stages of disease development.⁶ In addition, abnormalities in the T-cell receptor repertoire and T-cell clonotype of *bronchoalveolar lavage* (BAL) lymphocytes and peripheral blood lymphocytes might contribute to the pathophysiology of eosinophilic lung diseases.⁷⁻⁹

Recruitment of the eosinophil to the lung mostly implicates IL-5 and the eotaxin subfamily of chemokines (itself regulated by the Th2 cell–derived IL-13 cytokine). Release of toxic granule proteins and lipid mediators by eosinophils may contribute to tissue damage and dysfunction. Although histopathologic lesions related to the release of toxic granule proteins and lipid mediators in eosinophilic pneumonias are largely reversible with treatment, tissue damage and remodeling with fibrosis (partly through the release of transforming growth factor- β by eosinophils) associated with eosinophil infiltration can take place, especially in the bronchial mucosa, as in *allergic bronchopulmonary aspergillosis* (ABPA) and in *eosinophilic granulomatosis with polyangiitis* (Churg-Strauss syndrome) (EGPA [CSS]). Corticosteroids are the most effective agents for dramatically reducing

eosinophilia in the blood and tissues by shortening the half-life of cytokines such as eotaxins and inhibiting the cytokine-dependent survival of eosinophils.

Major impediments in eosinophil research are the inability of murine eosinophils to degranulate either in vivo or in vitro in contrast with human eosinophils that differentially release their granule proteins after contact with different stimuli and the limits of animal models in mimicking human eosinophilic lung disease. The availability of humanized anti-IL-5 antibody, which lowers eosinophil levels in the blood and in the lung in humans, as well as of genetically engineered mice such as those deficient in IL-5 or in eosinophils, has contributed to a better understanding of the pathogenic role of eosinophils.¹⁰ Recent advances in eosinophil biology and drug design have led to the design of a variety of potential therapeutic agents that target eosinophil-specific molecules and which are the focus of active research in patients with hypereosinophilic diseases.¹¹ The most promising targets currently being investigated include IL-5 and IL-5R, CD2 binding protein, *immunoglobulin E* (IgE), and IL-4/IL-13 receptor, with a few agents already evaluated or routinely used clinically.

GENERAL FEATURES OF EOSINOPHILIC PNEUMONIAS

HISTORICAL PERSPECTIVE

In 1952, Reeder and Goodrich¹² published a series of cases describing pulmonary “infiltration with eosinophilia,” including probable *idiopathic chronic eosinophilic pneumonia* (ICEP) and EGPA. Crofton and coworkers¹³ published in the same year a series of 16 cases of “pulmonary eosinophilia” with a review of 450 cases from the literature and proposed the following classification:

1. Simple pulmonary eosinophilia (Löffler syndrome), defined by mild symptoms and transient opacities.
2. Prolonged pulmonary eosinophilia characterized by radiographic shadows persisting for longer than 1 month.
3. Tropical eosinophilia.
4. Pulmonary eosinophilia with asthma (a rather heterogeneous category).
5. Polyarteritis nodosa.

The authors mentioned “a continuum from the simple and transient abnormalities of Löffler syndrome to the severe and often fatal manifestations of polyarteritis nodosa.” Churg and Strauss had reported in 1951¹⁴ the eponym syndrome of “allergic granulomatosis, allergic angiitis, and periarteritis nodosa,” and Carrington and colleagues¹⁵ described in 1969 the syndrome of ICEP. McCarthy and Pepys¹⁶ later reported 27 cases of “cryptogenic pulmonary eosinophilias,” 2 of whom developed systemic vasculitis.

CLINICAL PRESENTATION

Eosinophilic pneumonia is a pneumonia where the eosinophils are the most prominent inflammatory cells on histopathologic examination. Other inflammatory cells,

especially lymphocytes and neutrophils, are often associated, but eosinophils clearly predominate. In clinical practice, the eosinophilic pneumonias may be separated into two main etiologic categories: (1) those in which a definite cause is found or (2) those of undetermined origin, that is, idiopathic (with the eosinophilic pneumonia being either solitary or included in a systemic disorder such as EGPA).

A definite cause must be carefully investigated in any patient with eosinophilic pneumonia because it has practical consequences (e.g., stopping a drug responsible for iatrogenic eosinophilic pneumonia or treating a parasitic infection). When no cause is identified, the eosinophilic pneumonias may usually be included within well-characterized and individualized syndromes.

The eosinophilic pneumonias may manifest by different clinico-radiologic syndromes, namely Löffler syndrome, chronic eosinophilic pneumonia, or acute eosinophilic pneumonia, mostly differing from one another by the pattern of disease onset. Extrapulmonary manifestations accompanying eosinophilic pneumonia are the hallmark of EGPA and, to a lesser extent, *hypereosinophilic syndromes* (HESs), drug reactions, or infections, especially parasitic infections. The vast majority of cases of eosinophilic pneumonia respond dramatically to corticosteroid treatment and heal without significant sequelae.

PATHOLOGY

Histopathologic studies of eosinophilic pneumonia have mainly been done in patients with ICEP,^{15,17,18} which was initially diagnosed by open-lung biopsy. The pathologic features described in ICEP may be considered as a common denominator of all categories of eosinophilic pneumonias, whatever their origin. Occasionally, pathologic studies in eosinophilic pneumonias of known cause have further shown some specific features, such as a possible distinctive distribution of lesions (e.g., bronchocentric distribution in ABPA) or the presence of causal agents such as parasites or fungal hyphae.

In ICEP, the alveolar spaces are filled with eosinophils (Fig. 68-1). Macrophages are also present with some mul-

tinucleated giant cells scattered in the infiltrate; these may contain eosinophilic granules or Charcot-Leyden crystals.¹⁵ An associated interstitial inflammatory cellular infiltrate is invariably present, consisting of eosinophils, lymphocytes, plasma cells, and histiocytes. A proteinaceous and fibrinous exudate accompanies the cellular eosinophilic infiltrate. Some eosinophilic microabscesses may be observed (foci of necrotic intra-alveolar eosinophils surrounded by macrophages or epithelioid cells with palisading arrangement). Morphologic (especially electron microscopic) and immunohistochemical studies have shown eosinophil degranulation within the site of eosinophilic pneumonia.¹⁹ The global architecture of the lung remains intact, without necrosis or fibrosis.

Organization of the alveolar inflammatory exudate is a rather common finding,¹⁵ suggesting some possible overlap between ICEP and organizing pneumonia. However, intraluminal organization in the distal air spaces is only sparse and never prominent in ICEP. Mucus plugs obstructing the small airways may be present in ICEP.¹⁵ A mild *non-necrotizing* vasculitis involving both small arteries and venules is common, with perivascular cuffing and a few cells infiltrating the arterial media (Fig. 68-2).

The distribution of eosinophilic pneumonia is generally diffuse. However, it may be more focal in some cases, and the lesions may have an angiocentric or bronchiolocentric distribution in some etiologic groups of eosinophilic pneumonia. The hilar lymph nodes associated with ICEP contain many eosinophils, and lymphoid hyperplasia is present.¹⁵

In *idiopathic acute eosinophilic pneumonia* (IAEP), the pathologic pattern includes intra-alveolar and interstitial eosinophilic infiltrates, diffuse alveolar damage, intra-alveolar fibrinous exudates, organizing pneumonia, and non-necrotizing vasculitis (Fig. 68-3).²⁰

DIAGNOSIS

In clinical practice, the diagnosis of eosinophilic pneumonia is suspected in patients presenting with respiratory

Figure 68-1 Eosinophilic pneumonia. There is an accumulation of eosinophils (arrows) within the alveoli. (Courtesy Françoise Thivolet-Béjui, MD, Department of Pathology, Louis-Pradel Hospital and Claude Bernard University, Lyon, France.)

Figure 68-2 Eosinophilic pneumonia. Eosinophils have infiltrated the arteriolar wall (non-necrotizing vasculitis) (arrow) and are present within the alveoli (arrowheads). Figure 68-3 Acute eosinophilic pneumonia. **A**, In acute eosinophilic pneumonia, the alveolar spaces are diffusely filled with eosinophils and plump eosinophilic macrophages, sometimes with an associated mild interstitial pneumonia. In this low power view, multiple alveolar spaces are completely filled up to the pleural surface. **B**, Eosinophilic microabscesses (arrows) may be present. **C**, Fibrinous air space exudates (arrows) are commonly present, typically with admixed eosinophils, as seen in this specimen. **D**, Organizing pneumonia pattern with repair may also be seen (arrows). (From Leslie KO, Wick MR: Practical pulmonary pathology: a diagnostic approach: a volume in the pattern recognition series, ed 2. Philadelphia, 2011, Elsevier, Figs. 7-56 and 7-58.)

symptoms (dyspnea, cough, or wheezing); pulmonary opacities at chest imaging; and the demonstration of eosinophilia in the peripheral blood or, preferably, in the lung. Importantly, *blood eosinophilia* is defined by an eosinophil blood count greater than $0.5 \times 10^9/L$ ($500/\mu L$) and *hyper-eosinophilia* by an eosinophil blood count greater than $1.5 \times 10^9/L$ ($1500/\mu L$) on two examinations at least 1 month apart, and/or tissue hypereosinophilia.²¹

Although pathologic examination of the lung has been the “gold standard” to define eosinophilic pneumonia, surgical lung biopsy is almost abandoned and video-assisted thoracoscopic lung biopsy is seldom necessary. Transbronchial lung biopsy may show characteristic features of eosinophilic pneumonia, but the small size of the specimen usually does not allow morphologic evidence of a possible etiologic process.

BAL has become a widely accepted noninvasive surrogate of lung biopsy for the diagnosis in a patient with *high-resolution computed tomography* (HRCT) features of eosinophilic pneumonia, although no study has definitely established a correlation between increased eosinophils at differential cell count and the finding of eosinophilic pneumonia at lung pathology. In normal subjects, BAL eosinophilia is lower than 1% of cells at differential count.²² In contrast, BAL eosinophilia greater than 40% is found mainly in patients with chronic eosinophilic pneumonia, whereas BAL eosinophilia between 3% and 40% (and especially between 3% and 9%) may be found in various conditions, such as idiopathic pulmonary fibrosis, interstitial lung disease associated with connective tissue disorders,

hypersensitivity pneumonitis, sarcoidosis, radiation pneumonitis, asthma, pneumoconioses, and infection.²³

A conservative cutoff of 40% of eosinophils in the BAL has been adopted for the diagnosis of ICEP in clinical studies,^{24,25} and a cutoff of 25% has been proposed for the diagnosis of IAEP.²⁶ For clinical practice, our recommendation is that a diagnosis of eosinophilic pneumonia is supported by alveolar eosinophilia when the eosinophils (1) are the predominant cell population (macrophages excepted) and (2) represent more than 25% and preferably more than 40% of the differential cell count in the BAL.

Although BAL is usually a safe procedure, it may not always be mandatory in typical cases with both radiographic pulmonary opacities and peripheral blood eosinophilia, although alternative diagnoses can be considered (such as bacterial or parasitic pneumonia, or pulmonary opacities related to Hodgkin disease). However, diagnosing eosinophilic pneumonia on the sole finding of blood eosinophilia and pulmonary opacities requires markedly elevated eosinophilia ($>1 \times 10^9/L$ and preferably $1.5 \times 10^9/L$; >1000 and preferably $1500/\mu L$) together with typical clinicoradiologic features, because the finding of peripheral blood eosinophilia does not prove that the observed pulmonary opacities correspond to eosinophilic pneumonia. For example, BAL may occasionally be omitted for the diagnosis of Löffler syndrome (as it is seen in ascariasis), with rather mild and nonspecific cough and wheezes, transient pulmonary opacities at chest radiography, and frank blood eosinophilia. Conversely, peripheral blood eosinophilia may be missing in patients who have already received systemic

corticosteroids, and it is often absent at presentation in IAEP. Nevertheless, BAL is recommended to confirm the diagnosis of eosinophilic pneumonia in most cases.

Once the diagnosis of eosinophilic pneumonia has been made, a thorough evaluation is necessary to investigate possible causes, such as parasitic infection or drug or toxic exposure, and to classify the case into one of the possible clinical entities (see Table 68-1).

EOSINOPHILIC LUNG DISEASE OF UNDETERMINED CAUSE

ICEP is characterized by a progressive onset of symptoms over a few weeks with cough, increasing dyspnea, malaise, and weight loss, whereas IAEP presents as an acute pneumonia (similar to acute lung injury or *acute respiratory distress syndrome* [ARDS]) with frequent respiratory failure necessitating mechanical ventilation. Both conditions are idiopathic.

IDIOPATHIC CHRONIC EOSINOPHILIC PNEUMONIA

Idiopathic chronic eosinophilic pneumonia (ICEP) was first described in detail by Carrington and colleagues,¹⁵ in a series of nine patients, and further confirmed and detailed by several series^{18,25,27-29} and numerous case reports.

Clinical Features

ICEP arises predominantly in women (with a 2:1 female-to-male ratio).^{18,25} Although ICEP may develop in young people,^{30,31} only 6% of patients are younger than 20 years old.^{18,31a} The incidence of ICEP peaks in the fourth decade,¹⁸ with a mean age of 45 years at diagnosis.²⁵ A vast majority of patients with ICEP are nonsmokers,^{18,25,28} suggesting that smoking might be protective. A prior history of atopy is found in about half of the patients, with allergic rhinitis in 12%¹⁸ to 24%,²⁵ drug allergy in about 10%,^{18,25} nasal polyps in 5%¹⁸ to 13%,²⁵ urticaria in 10%,²⁵ and eczema in 5%.²⁵

Prior asthma is present in up to two thirds of the patients.^{17,18,24,25,28,29} Asthma may also develop concomitantly with the diagnosis of ICEP in 15% of patients or develop after ICEP in 13%.²⁴ The presentation of ICEP is similar in asthmatic and nonasthmatic patients with the exception of higher total IgE in the former group.²⁴ ICEP may develop while asthmatic patients are on a desensitization program, but there is no proof that desensitization may contribute to the development of ICEP. Asthma often gets worse after the development of ICEP and requires long-term oral corticosteroid treatment even in the absence of recurrence of the eosinophilic pneumonia.²⁴

The onset of ICEP is progressive, with a mean interval between the onset of symptoms and the diagnosis of 4 months in one series.²⁵ The most common respiratory symptoms are cough, dyspnea, and chest pain.^{18,25} Dyspnea is usually not severe initially, although the necessity for mechanical ventilation after several months of progression of disease has occasionally been reported.³² Hemoptysis is rare but has been reported in up to 10% of cases.^{18,25}

Wheezes at physical examination are found in one third of patients¹⁸ and crackles in 38%.²⁵ Upper respiratory tract symptoms of chronic rhinitis or sinusitis are present in about 20% of patients.²⁵

Systemic symptoms and signs are often prominent, with fever, weight loss (>10 kg in about 10%). Asthenia, malaise, fatigue, anorexia, weakness, and night sweats are also common.

Imaging

The imaging features of ICEP are characteristic, although they may overlap with those found in cryptogenic organizing pneumonia (see Chapter 63). Peripheral opacities on chest radiography are present in almost all cases^{15,18,25,33-36} and are migratory in a quarter of the cases.²⁵ They usually consist of alveolar opacities with ill-defined margins, with a density varying from ground-glass to consolidation (Fig. 68-4, eFig. 68-1). The classic pattern of “photographic negative or reversal of the shadows usually seen in pulmonary edema,”³⁵ highly evocative of ICEP,³⁵ is seen in only one fourth of patients.¹⁸

Characteristic imaging features of ICEP are better described at HRCT (Fig. 68-5). Whereas the opacities are bilateral in at least 50% of cases at chest radiography,^{18,28} the proportion of bilateral opacities may increase up to 97.5% at HRCT.²⁵ Characteristic opacities predominate in the upper lobes^{18,25,33} and are peripheral, with generally coexisting ground-glass and consolidation opacities at HRCT (Video 68-1).^{25,34,37,38} Midzone distribution of opacities and centrilobular nodules are present in less than 20% of cases.³⁸ Consolidation with segmental or lobar atelectasis may be seen.³⁴ Septal line thickening is common (see Video 68-1).³⁷ On corticosteroid treatment, consolidation and ground-glass opacities rapidly show a decrease in size and extent (eFig. 68-2), with possible change from consolidation to ground-glass opacities or inhomogeneous opacities, and later to streaky or bandlike opacities parallel to the

Figure 68-4 Idiopathic chronic eosinophilic pneumonia. Chest radiograph of a patient with idiopathic chronic eosinophilic pneumonia shows bilateral alveolar opacities predominating in the upper lobes.

Figure 68-5 Idiopathic chronic eosinophilic pneumonia. Axial chest CT scan of a patient with idiopathic chronic eosinophilic pneumonia shows bilateral symmetrical peripheral alveolar opacities.

chest wall.³⁴ Cavitory lesions are extremely rare and should lead to reconsideration of the diagnosis. Contrary to organizing pneumonia, the reverse halo or atoll sign (i.e., central ground-glass opacity surrounded by denser consolidation in a crescentic circle or ring) is rare. Compared with IAE, in which pleural effusions are seen in the majority (see later), small pleural effusions are present in only 10% of cases of ICEP at HRCT and mediastinal lymph node enlargement in 17%.²⁵

Laboratory Studies

Peripheral blood eosinophilia over 6% was present in 88% of 111 cases in one literature review,¹⁸ with a mean percentage of blood eosinophils at differential count of 26%. The mean blood eosinophilia was $5.5 \times 10^9/L$ (5500/ μL) in our series, with eosinophils representing a mean of 32% of the total blood leukocyte count.²⁵ Because peripheral blood eosinophilia is often a diagnostic criterion of ICEP, the proportion of patients with ICEP and possible normal peripheral blood count is unknown.

Erythrocyte sedimentation rate is increased, and C-reactive protein level is elevated.^{18,25,28} Total blood IgE level is increased in about half of cases and greater than 1000 IU/mL in 15% (normal < 100 IU/mL).²⁵ Circulating immune complexes have been reported in ICEP in about one third of patients.²⁵ Antinuclear antibodies may occasionally be present.²⁵ Urinary eosinophil-derived neurotoxin level indicating active eosinophil degranulation is markedly increased.³⁹

Bronchoalveolar Lavage

BAL has replaced lung biopsy for the diagnosis of ICEP. Alveolar eosinophilia is a characteristic and constant feature in ICEP,^{25,40} with a mean of 58% at differential cell count.²⁵ Alveolar eosinophilia may be associated with an increased percentage of neutrophils, mast cells, and lymphocytes.²⁵ BAL eosinophil cell count drops within a few days under corticosteroid treatment.⁴¹ Sputum eosinophilia may also be present.^{13,29}

BAL eosinophils of patients with ICEP show activation features such as the release of eosinophil proteins, which

are taken up by macrophages.⁴² Eosinophil cationic protein⁴³ and eosinophil-derived neurotoxin⁴³ are increased in BAL fluid of patients with ICEP. Expression of HLA-DR in a patient with ICEP was present on 86% of alveolar eosinophils in contrast to 7% of blood eosinophils, suggesting compartmentalization of eosinophilic activation within the lung.⁴⁴ BAL lymphocytes are characterized by an accumulation of CD4⁺ T cells that express activation surface antigens of memory T cells (CD45RO⁺, CD45RA⁻, CD62L⁻),⁴⁵ and may present clonal rearrangement of the T-cell receptor repertoire.^{8,46} Recruitment of eosinophils to the lung involves various chemokines, which contribute to suppress Fas-induced apoptosis of eosinophils.⁴⁷

Differential Diagnosis

Although ICEP is not a systemic disease, isolated and moderately severe extrapulmonary manifestations, including arthralgias, repolarization (ST-T) abnormalities on the electrocardiogram, pericarditis, altered liver biologic tests, eosinophilic lesions at liver biopsy, mononeuritis multiplex, diarrhea, skin nodules, immune complex vasculitis in the skin, and eosinophilic enteritis, have been reported occasionally.^{15,25,48} Such manifestations suggest an overlap between ICEP and EGPA. Eosinophilic pneumonia similar to ICEP may be a presenting feature of EGPA^{49,50} with patients often receiving corticosteroid treatment, which may prevent the development of overt systemic vasculitis. In a series of ICEP with especially high frequency of extrapulmonary signs (30%), some of which were quite evocative of EGPA, none of the patients treated with corticosteroids developed characteristic EGPA or HES on follow-up.⁴⁸

Lung Function Tests

Lung function tests in ICEP show an obstructive ventilatory defect in about half the patients^{18,25} and a restrictive ventilatory defect in half the cases.²⁵ Hypoxemia defined by an arterial oxygen pressure arterial (PO₂) of 75 mm Hg or less was present in 64% of patients in a series²⁵; CO transfer factor (diffusing capacity DL_{CO}) was less than 80% of predicted in 52%, and transfer coefficient (DL_{CO} per unit alveolar volume) was less than 80% of predicted in only 27%. An increased alveolar-arterial oxygen difference has been reported in 90% of cases.¹⁸ The impaired lung function tests normalize under treatment in most patients.¹⁸ However, a ventilatory obstructive defect may develop over time in some patients, especially those with a markedly increased BAL eosinophilia at initial evaluation.⁵¹

Treatment and Prognosis

The natural course of untreated ICEP is not well known because most patients receive corticosteroids with a dramatic response.¹⁸ ICEP may spontaneously resolve,^{18,25} and death directly resulting from ICEP is exceedingly rare. Symptoms improve within 1 or 2 weeks of corticosteroid treatment and even within 48 hours in about 80%²⁵ of cases. Pulmonary opacities on chest radiography clear rapidly (eFig. 68-3). They disappeared within 1 week in 69% of patients in our series of patients treated with a mean initial dose of 1 mg/kg/day, and almost all patients treated with corticosteroids had a normal chest radiograph at their last follow-up visit.²⁵

The optimal dose of corticosteroids is not established, but the usual doses vary between 20 and 60 mg/day. Our current recommendation is to start with 0.5 mg/kg/day of prednisone, with slow tapering over 6 to 12 months based on clinical evaluation and blood eosinophil cell count. Most patients require prolonged treatment (i.e., >6 months) because of relapse while decreasing below a daily dose of 10 to 15 mg/day of prednisone, or after stopping the corticosteroid treatment. In one series, 58% of cases relapsed after corticosteroids had been discontinued and 21% while the corticosteroids were being tapered.¹⁸ In our series, half of the patients relapsed after the corticosteroids had been weaned (with a mean delay of 72 weeks) or were being tapered (the mean dose of corticosteroids at the time of relapse was 11 mg/day).²⁵ Relapses in the same areas of the lungs or in different areas²⁵ respond well to resumed corticosteroid treatment; a dose of 20 mg/day of prednisone is usually sufficient to treat the relapses.

The clinical series in which follow-up is available clearly show that most patients need very prolonged corticosteroid treatment: in our series with a mean 6.2 years of follow-up, only 31% were weaned at the last control visit.²⁵ Respiratory symptoms may be due to asthma or to ICEP relapse. Relapses of ICEP are less frequent in patients with asthma, possibly because they often receive inhaled corticosteroids after stopping oral corticosteroids.^{24,25} Inhaled corticosteroids might thus help in reducing the maintenance dose of oral corticosteroids, although they are not sufficient when given as monotherapy.⁵² Long-term steroid use may lead to osteoporosis. Omalizumab, a recombinant humanized monoclonal antibody against IgE, has been suggested in case reports to prevent recurrence of ICEP and to spare oral corticosteroids^{53,54}; however, caution must be exerted given recent reports of omalizumab-associated EGPA.^{55,56} Mepolizumab, a monoclonal antibody against IL-5, has not yet been evaluated in patients with ICEP.

IDIOPATHIC ACUTE EOSINOPHILIC PNEUMONIA

Idiopathic acute eosinophilic pneumonia (IAEP) differs from ICEP by its acute onset, the severity of hypoxemia, the usual lack of increased blood eosinophils at presentation contrasting with frank eosinophilic alveolitis at BAL (BAL differential count with $\geq 25\%$ eosinophils or predominance of eosinophils in open lung biopsy), and the absence of relapse after clinical recovery.^{20,26,29,57-60} Because fever and bilateral opacities on chest radiograph are present in all patients, IAEP is often misdiagnosed as infectious pneumonia and its frequency may therefore be underestimated. The absence of hypersensitivity to drugs, historical or laboratory evidence of infection, and other known causes of acute eosinophilic lung disease are additional diagnostic criteria.²⁶ Current diagnostic criteria of IAEP are listed in Table 68-2.⁶¹

Clinical Features

The average age at presentation is about 30 years,^{26,60} but IAEP may develop in patients age 20 or younger³⁰ and in older patients.⁶⁰ In contrast with ICEP, it is seen almost exclusively in males,⁶² and most patients have no prior asthma history.²⁹

Table 68-2 Diagnostic Criteria for Idiopathic Acute Eosinophilic Pneumonia

1. Acute onset of febrile respiratory manifestations (≤ 1 mo duration before consultation)
2. Bilateral diffuse opacities on chest radiography
3. Hypoxemia, with PaO_2 on room air < 60 mm Hg, and/or $\text{PaO}_2/\text{FiO}_2 \leq 300$ mm Hg, and/or oxygen saturation on room air $< 90\%$
4. Lung eosinophilia, with $> 25\%$ eosinophils on BAL differential cell count (or eosinophilic pneumonia at lung biopsy)
5. Absence of infection or of other known causes of eosinophilic lung disease (especially exposure to a drug susceptible to induce pulmonary eosinophilia)

Adapted from Allen JN, Pacht ER, Gadek JE, Davis WB: Acute eosinophilic pneumonia as a reversible cause of noninfectious respiratory failure. *N Engl J Med* 321:569–574, 1989; and Cottin V, Cordier JF: Eosinophilic pneumonias. *Allergy* 60:841–857, 2005.

Importantly, most patients seem to have been exposed to dust or cigarette smoke within the days before onset of disease. Some patients had peculiar outdoor activities, such as cave exploration, plant repotting, wood pile moving, smokehouse cleaning, motocross racing in dusty conditions, indoor renovation work, gasoline tank cleaning, and explosion of a tear gas bomb.^{26,60} One case was also reported in a New York City firefighter exposed to World Trade Center dust.⁶³

A causative role of cigarette smoke seems established because IAEP has developed soon after the initiation of smoking (especially when starting with large quantities) in numerous patients,⁶⁴⁻⁶⁹ and challenge with cigarette smoking was positive in some of them,^{64-67,69} but tolerance may develop in patients who resume smoking.⁶⁵⁻⁶⁷ Flavoring components of smoked cigars have been suspected.⁷⁰ Recent alterations in smoking habits (e.g., beginning to smoke, restarting, or increasing the number of cigarettes smoked daily) especially within 1 month (median delay, 2 weeks) seem to play a major role in the onset of “idiopathic” AEP.^{62,69} Passive smoking has also been reported to cause AEP.⁷¹ It is likely that inhalation of tobacco smoke or of any nonspecific injurious agent may initiate or contribute to the development of IAEP in individuals intrinsically prone to develop eosinophilic reactions to inhaled nonspecific causative agents. Increased levels of $\beta(1 \rightarrow 3)$ -D-glucan (a major component of the cell wall of most fungi and also one of the components of cigarette smoke) have been reported in BAL fluid of patients with IAEP.⁶⁸

IAEP develops acutely in previously healthy individuals, with symptoms at presentation consisting of cough, dyspnea, fever, and chest pain. It may also develop subacutely over a few weeks,²⁰ with no clinical difference between patients seen in a time interval of less than 7 days or 7 to 31 days from the first symptoms to the diagnosis of IAEP.⁶⁰ More than half of patients present with acute respiratory failure.⁶² Abdominal complaints and also myalgias have been reported.²⁶ At physical examination, tachypnea and tachycardia are present, with crackles or, less often, wheezes on auscultation.

Imaging

The chest radiograph shows bilateral opacities, with mixed alveolar or interstitial opacities (eFig 68-4A-B, G).^{26,58-60} In contrast with ICEP, bilateral pleural effusion and Kerley B

lines are common.²⁶ The chest radiograph returns to normal within 3 weeks (see eFig. 68-4L),^{26,58} with pleural effusions being the last abnormality to disappear.²⁶

At chest CT imaging, ground-glass opacities and air space consolidation are the most common patterns of parenchymal lesions, with poorly defined nodules and interlobular septal thickening seen in a majority of patients; pleural effusion is present in at least two thirds of patients and is usually bilateral (see eFig. 68-4C-E, H-K).^{26,36,58,60,72} We consider that bilateral pleural effusion and interlobular septal thickening are highly characteristic of IAEP in a patient with eosinophilic pneumonia; in addition, they should raise the suspicion of IAEP in a patient considered to have infectious pneumonia.

Laboratory Studies

In contrast with ICEP, the white blood cell count at presentation usually shows an increased leukocyte count with a predominance of neutrophils, with eosinophils only rarely higher than $0.3 \times 10^9/L$ ($300/\mu L$), but the eosinophil count often rises to high values later during the course of disease,^{26,29,60} a retrospective finding suggestive of IAEP. Eosinophilia is also present in the pleural fluid^{26,65,73} and sputum.²⁹

The IgE level may be elevated in some patients,^{73,74} and serum IgG and especially IgG2 and IgG4 levels may be reduced during the active phase of disease as compared with controls,⁷⁴ although with limited diagnostic value. Serum levels of *thymus and activation-regulated chemokine* (TARC/CCL17), KL6, or exhaled nitric oxide are often increased in IAEP as opposed to other causes of acute lung injury or infectious pneumonia; these biomarkers are not specific for IAEP, however.^{75,76}

Bronchoalveolar Lavage

Given the usual lack of initial blood eosinophilia, BAL is the key to the diagnosis of IAEP, showing an average percentage of 37%²⁶ to 54%⁶⁰ eosinophils on the differential cell count, with sterile bacterial cultures. Lymphocyte and neutrophil counts can be moderately increased. After recovery, eosinophilia in the BAL may persist for several weeks.⁷⁷ We consider that the finding of eosinophilia greater than 25% at BAL may obviate the need for lung biopsy for diagnosis, at least in immunocompetent patients.

Lung Function Tests

Hypoxemia may be severe and refractory to breathing 100% oxygen, suggesting right-to-left shunting in some patients.^{57,60} A majority of patients fit the definition of ARDS of various severity (e.g., acute onset of respiratory failure not fully explained by cardiac failure or fluid overload, with objective exclusion of hydrostatic edema); bilateral opacities (not fully explained by effusions, lobar/lung collapse, or nodules); and an arterial PO_2/FIO_2 (fractional inspired oxygen concentration) < 300 mm Hg with positive end-expiratory pressure or continuous positive expiratory pressure greater than or equal to 5 cm H_2O .⁷⁸ Mechanical ventilation, either noninvasive or with intratracheal intubation, was necessary in a majority of patients in earlier series.^{26,60} More recent series have shown that the severity of IAEP is more varied than originally reported.⁶² In contrast with ARDS, shock is extremely unusual^{79,80} and extrapulmonary organ failure is not seen. FIO_2 may be decreased

within a few hours of steroid treatment in many patients initially requiring oxygen.²⁶

When performed in less severe cases, lung function tests have shown a mild restrictive ventilatory defect with normal *forced expiratory volume in 1 second*–to–*forced vital capacity* (FEV_1/FVC) ratio and reduced transfer factor (diffusing capacity).⁷⁴ Alveolar-arterial oxygen gradient is increased.²⁶ Lung function tests performed after recovery are normal in most patients, with possible ventilatory restriction in some of them.^{26,81,82}

Lung Biopsy

Lung biopsy is seldom necessary when BAL is performed. When done, it shows acute and organizing diffuse alveolar damage together with interstitial alveolar and bronchiolar infiltration by eosinophils, intra-alveolar eosinophils, and interstitial edema.^{20,26,79,83}

Treatment and Prognosis

Recovery without corticosteroid treatment has been reported,^{60,75} and therefore improvement concomitant with corticosteroid treatment cannot be considered a diagnostic criterion of IAEP. However, when a diagnosis of IAEP is made, corticosteroid treatment is usually started with initially intravenous methylprednisolone and later changed to oral therapy that can be tapered over 2 to 4 weeks.²⁶ The patient generally responds to corticosteroids within 3 days (see eFig. 68-4L)⁶² and can be rapidly weaned from the ventilator and from oxygen supplementation. The chest radiograph normalizes within 1 week in 85% of patients, but mild pulmonary opacities and pleural effusion may still be present on chest *computed tomography* (CT) at 2 weeks.⁶² One recent study of 137 patients suggested that a treatment duration of 2 weeks may be sufficient, with an initial daily dose of 30 mg of prednisone (or 60 mg of intravenous methylprednisolone every 6 hours in patients with respiratory failure).⁶² Recovery is rapid with no significant clinical or imaging sequelae, and with no relapse after stopping corticosteroid treatment, in contrast with ICEP where relapse is common.

Although IAEP often presents clinically like acute lung injury or ARDS, its prognosis is far better. The key to the diagnosis is finding eosinophilia on BAL because blood eosinophilia is usually absent initially. A careful search for a cause of AEP is mandatory, and infectious agents must be sought for in BAL fluid by cultures and appropriate staining.⁸⁴⁻⁸⁶ Drug-induced AEP must also be carefully excluded. Identification of causative tobacco or environmental exposures is key to preventing rare recurrences that in most cases are due to resumption of cigarette smoking after smoking cessation.

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS

History and Nomenclature

The first reliable case of *eosinophilic granulomatosis with polyangiitis* (EGPA) was reported by Lamb⁸⁷ in 1914. Churg and Strauss¹⁴ described in 1951 the eponymous syndrome, mainly from autopsied cases. They described characteristic pathologic features consisting of granulomatous extravascular lesions, as well as necrotizing, inflammatory, and

granulomatous vascular changes, with an inflammatory exudate rich in eosinophils. The most frequent site of inflammation was the heart. In approximately half of the cases, a pneumonic process was found, with an eosinophil-rich exudate mixed with giant cells in the acute stage.

In the 1992 Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis,⁸⁸ CSS was included in the group of small vessel vasculitides. In 2012, the nomenclature of the systemic vasculitides was revised at the International Chapel Hill Consensus Conference.⁸⁹ The eponym CSS was replaced by the terminology of eosinophilic granulomatosis with polyangiitis to achieve nomenclature symmetry with microscopic polyangiitis and with granulomatosis with polyangiitis (Wegener), which are the pulmonary *antineutrophil cytoplasmic antibody* (ANCA)-associated vasculitides, together with single-organ, ANCA-associated vasculitis.

EGPA is defined as an eosinophil-rich and necrotizing granulomatous inflammation often involving the respiratory tract and a necrotizing vasculitis predominantly affecting small to medium vessels, associated with asthma and eosinophilia. It is acknowledged that the disease may be confined to a limited number of organs, especially the upper or lower respiratory tract.⁸⁹ This terminology reminds us that EGPA is indeed a vasculitis; however, not all patients with EGPA have robust criteria of documented systemic vasculitis or the presence of ANCA.⁹⁰ ANCAs are present in approximately 40% of the cases. ANCAs are more frequent when glomerulonephritis is present, and most patients with

documented necrotizing glomerulonephritis have ANCAs.⁹¹ Therefore the current revised terminology and classification may require further refinement.

Pathology

Because the diagnosis is now made earlier in the course of disease, lung biopsy is seldom necessary, and patients may receive corticosteroids before overt vasculitis has developed. The pathologic lesions of EGPA currently observed^{92,93} only rarely comprise all the characteristic features on a single biopsy from one organ. When typical features are present, both vasculitis (necrotizing or not, involving mainly the medium-sized pulmonary arteries) and granulomatous eosinophilic infiltration are seen (Fig. 68-6A-B). The extravascular granuloma consists of palisading histiocytes and giant cells (see Fig. 68-6C). Diffuse pulmonary hemorrhage with capillaritis can develop (see Fig. 68-6D). When present, the eosinophilic pneumonia in EGPA is similar to ICEP. The early (prevasculitic) phase of EGPA is characterized by eosinophilic infiltration of the tissues without vasculitis (perivascular eosinophils are commonly found).

Clinical Features

The clinical features of EGPA have been well defined.⁹⁴⁻⁹⁹ It is a rare systemic disease, which presents especially in adults younger than 65^{98,100}; it has been occasionally reported in children and adolescents.^{100a} There is no sex predominance. The mean age of onset of vasculitis ranges from 38 to 49 years.^{98,101}

Figure 68-6 Eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome) (EGPA) **A**, Vasculitis. A medium-sized artery infiltrated by eosinophils and scattered lymphocytes. **B**, Vasculitis. A venule infiltrated by eosinophils. Note fibrin and eosinophils in surrounding air spaces. **C**, Eosinophilic granulomas. Characteristic "allergic granuloma" is readily apparent. Note the vaguely palisaded histiocytes at the periphery of eosinophilic necrosis (center). Multinucleate giant cells may be present and typically have a brightly eosinophilic cytoplasm. **D**, Pulmonary hemorrhage. Diffuse pulmonary hemorrhage with capillaritis can be seen in EGPA. Capillaritis is demonstrated here, associated with aggregated air space fibrin and eosinophils. (From Leslie KO, Wick MR: Practical pulmonary pathology: a diagnostic approach: a volume in the pattern recognition series, ed 2. Philadelphia, 2011, Elsevier, Figs. 10-27, 10-29, and 10-28.)

Asthma, generally severe and becoming rapidly corticosteroid dependent, presents at a mean age of about 35.⁹⁸ It usually precedes the onset of vasculitis by 3 years and up to 9 years.^{94,98,101,102} The interval between asthma and the onset of vasculitis may be much longer in rare cases,¹⁰² or they may be contemporaneous.¹⁰¹ The severity of asthma typically increases progressively until the vasculitis develops, but it may attenuate when the vasculitis flourishes and further increase once the vasculitis recedes.^{98,102}

Chronic rhinitis is present in about three quarters of cases of EGPA^{98,103,104} and is often accompanied by relapsing sinusitis and/or polyposis, with eosinophilic infiltration seen on histopathology.¹⁰⁵ Paranasal sinusitis has been reported in 61% of patients.⁹⁴ Crusty rhinitis may be present, but the rhinitis in EGPA is distinctly much less severe than in granulomatosis with polyangiitis, with septal nasal perforation or saddle nose deformation being unusual.

Asthenia, weight loss, fever, arthralgias, and myalgias (all of which are unusual in simple asthma) often herald the development of the extrapulmonary manifestations of vasculitis.

Heart damage, which may be severe and lead to cardiac failure or sudden death,^{94,98,99,101,102,106} results especially from eosinophilic myocarditis and much less commonly from coronary arteritis.^{107,108} Cardiac involvement is often insidious and asymptomatic and, thus may be recognized only when left ventricular failure and dilated cardiomyopathy have developed. Heart failure may require heart transplantation,^{108a} but eosinophilic vasculitis may recur in the transplanted heart. However, myocardial impairment and coronary arteritis may markedly improve with corticosteroid treatment, thus necessitating a strict cardiac evaluation in any patient with suspected EGPA, including electrocardiogram, echocardiography, serum level of troponin, and *magnetic resonance imaging* (MRI) of the heart.¹⁰⁹ The main practical difficulty is the absence of a gold standard to diagnose clinically relevant myocardial involvement. Cardiac MRI can frequently demonstrate late enhancement of the myocardium¹¹⁰⁻¹¹²; however, it remains difficult to differentiate irreversible lesions representing scarring from active inflammation requiring intense immunosuppression; the combination of cardiac MRI with positron emission tomography may be useful but deserves further study.¹¹³

Pericarditis with limited effusion at echocardiography is common; tamponade is rare. In contrast with the idiopathic HES, endomyocardial involvement is not a common feature. Patients with EGPA are at greater risk of venous thromboembolic events.¹¹⁴

Peripheral neurologic involvement mainly consists of mononeuritis multiplex, present in 77% of patients,⁹⁴ or asymmetrical polyneuropathy, with sudden onset of painful, focal or multifocal weakness or sensory loss, generally in the lower extremities. Cranial nerve palsies and central nervous system involvement are rare. Digestive tract involvement is present in 31% of cases⁹⁴ and usually manifests as isolated abdominal pain, but intestinal or biliary tract vasculitis may be present. Other digestive manifestations include diarrhea; ulcerative colitis; gastroduodenal ulcerations; perforations (esophageal, gastric, intestinal); digestive hemorrhage; and cholecystitis. Cutaneous lesions, which present in about half of patients,⁹⁴ mainly consist of palpable purpura of the extremities, subcutaneous nodules (especially of the scalp and extremities), erythematous rashes, and urticaria. Renal involvement presents in 26% of cases and is usually mild,⁹⁴ in contrast with the other ANCA-associated vasculitides.

Imaging

Pulmonary opacities corresponding to eosinophilic pneumonia represent the most typical abnormalities on chest radiograph and have been reported in large series with a frequency of 37%⁶⁹ to 72% (see [eFig. 60-9A](#)).^{98,115} The pulmonary opacities are usually noted at presentation, but the chest radiograph remains normal throughout the course of the disease in some patients. The pulmonary opacities usually consist of ill-defined opacities, sometimes migratory, transient, and of varying density.^{98,102,116-118} In contrast to *granulomatosis with polyangiitis* (GPA), pulmonary cavitary lesions are extremely unusual. Pleural effusion (usually mild) and phrenic nerve palsy may be observed.

The pulmonary opacities on thin-section chest CT mainly consist of areas of ground-glass attenuation (see [eFig. 60-9B-E](#)) or air space consolidation, with peripheral predominance or random distribution ([Fig. 68-7](#)); centrilobular nodules are more frequent than in patients with ICEP³⁸; less common findings include bronchial wall thickening or dilation, interlobular septal thickening (see [eFig. 60-9B-E](#)),

Figure 68-7 Eosinophilic granulomatosis with polyangiitis. Axial chest CT scan of patients with eosinophilic granulomatosis with polyangiitis shows ground-glass opacity of the right upper lobe (**A**) and bilateral central and peripheral opacities with varying density (**B**).

Figure 68-8 Eosinophilic granulomatosis with polyangiitis. Axial chest CT scan of a patient with eosinophilic granulomatosis with polyangiitis, with lung consolidation and ground-glass opacities corresponding to eosinophilic pneumonia. In addition, pericardial effusion and bilateral pleural effusions are present due to cardiomyopathy.

hilar or mediastinal lymphadenopathy, pleural effusion, or pericardial effusion^{36,117-119} (Fig. 68-8). When present, pleural effusion should lead one to consider both inflammatory eosinophilic exudate and transudate with cardiomyopathy as a possible cause. Because these abnormalities are nonspecific, a correct diagnosis of EGPA was made on CT in only 44% of 111 patients with eosinophilic lung diseases.³⁶

Laboratory Studies

Peripheral blood eosinophilia is a major feature of EGPA that usually parallels the activity of the vasculitis. Blood eosinophils are generally between 5 and $20 \times 10^9/L$ (5000 to 20,000/ μL), but they may reach higher values.^{94,98,102} Blood eosinophilia often disappears dramatically after the initiation of corticosteroid treatment (which may thus cause the absence of eosinophilia if blood tests are not done before starting corticosteroid treatment). Eosinophilia, sometimes greater than 60%, is found on BAL differential cell count¹²⁰ and in pleural fluid when present.¹²¹

The ANCAs reported in about 40% of patients are mainly *perinuclear antineutrophil cytoplasmic antibodies* (p-ANCAs) with myeloperoxidase specificity (much less often *cytoplasmic antineutrophil cytoplasmic antibody* [c-ANCA] with proteinase 3 specificity).^{94,101,122-124} Serum IgE levels are markedly increased. The erythrocyte sedimentation rate and C-reactive protein level are increased, and anemia is common. High levels of urinary eosinophil-derived neurotoxin have been reported, and these might represent an activity index of disease.¹²⁵ Serum IgG4, CCL17/TARC, CCL26/Eotaxin-3 levels are elevated in active disease, but these have not been validated as biomarkers.¹²⁶⁻¹²⁹

Pathogenesis

The pathophysiology of EGPA is not established. EGPA may be considered as an autoimmune process involving T cells, endothelial cells, and eosinophils. Recent studies have identified possible defects in regulatory CD4⁺, CD25⁺, or CD4⁺CD25⁻ T-cell lymphocytes (producing IL-10 and IL-2) in EGPA (as compared with ICEP), possibly influencing progression and prognosis of disease.¹³⁰ Clonal CD8⁺/V β ⁺ T-cell

expansions with effector memory phenotype, showing markers of cytotoxic activity and consistent with a hypothesis of persistent antigenic stimulation, were found in peripheral blood lymphocytes by flow cytometry combined to analysis of *T-cell antigen receptor* (TCR)- γ gene rearrangement.^{131,132,132a} T-cell receptor-C beta gene rearrangement were reported.⁹ Some triggering or adjuvant factors (such as vaccines or desensitization) have been suspected to play a role in EGPA.^{133,134} The hypothesis of defective apoptosis pathways in eosinophils has not been confirmed.¹³⁵

Although a family history of atopy and allergic rhinitis is often present, evidence of allergy (demonstration of specific IgE with corresponding clinical history) is present in less than one third of patients; when present, allergy in EGPA mainly consists of perennial allergies, especially to *Dermatophagoides*, with seasonal allergies less frequent than in asthmatic patients without EGPA.¹³⁶ A genetic predisposition to develop EGPA has been demonstrated in patients carrying the major histopathology complex DRB4 allele¹³⁷ and perhaps in certain families.¹³⁸

Other possible triggering factors include *Aspergillus*, allergic bronchopulmonary candidiasis, *Ascaris*, bird exposure, or smoked cocaine. Drug-induced eosinophilic vasculitis with pulmonary involvement has been reported in the past with sulfonamides used together with antiserum, and later with diflunisal,¹³⁹ macrolides,¹⁴⁰ and diphenylhydantoin.¹⁴¹ EGPA has also been reported in asthmatic patients treated with omalizumab, an anti-IgE antibody.¹⁴²⁻¹⁴⁵

The possible responsibility of leukotriene-receptor antagonists (montelukast, zafirlukast, pranlukast) in the development of EGPA has generated much debate.^{101,146-150} Although the association between leukotriene receptor antagonists and EGPA is now established, there is conflicting evidence whether it is the result of confounding by indication or a genuine causal association.^{56,149} Whether the association is coincidental, whether some cases of smoldering EGPA flare because of reducing oral or inhaled corticosteroids and/or adding leukotriene receptor antagonists, or whether these drugs really exert a role on the pathogenesis of the vasculitis is not established. A possible mechanistic link has been proposed.¹⁵¹ However, EGPA may follow montelukast treatment in the absence of preexisting disease, may recur on rechallenge with leukotriene receptor antagonists, and may remit on withdrawal of this treatment without modifying the corticosteroid and/or immunosuppressive therapy.^{147,149} At least one recent study indicates that a causal relationship cannot be totally dismissed.¹⁵² We therefore consider that leukotriene receptor antagonists should be avoided in any asthma patient with eosinophilia and/or extrapulmonary manifestations compatible with smoldering EGPA.

Diagnosis

The diagnosis of EGPA may be difficult because the clinician nowadays is more often faced with patients presenting with early and mild signs corresponding to the so-called formes frustes of EGPA, which are more or less suppressed by corticosteroid treatment for asthma and which may later be unmasked, especially when treatment is reduced or stopped.

The evolution of EGPA usually follows three stages: asthma and rhinitis; tissue eosinophilia (such as a pulmonary disease resembling ICEP); and extrapulmonary

Table 68-3 Distinct Phenotypes of Eosinophilic Granulomatosis with Polyangiitis (Churg-Strauss Syndrome)

	Vasculitic Phenotype	Tissular (Tissue) Phenotype
Respective frequency	≈40%	≈60%
ANCA	Present (mostly p-ANCA with anti-MPO specificity)	Absent
Predominant clinical features	Glomerular renal disease Peripheral neuropathy Purpura	Cardiac involvement (eosinophilic myocarditis) Fever
Predominant histopathologic features	Biopsy-proven vasculitis	Eosinophilic pneumonia

ANCA, antineutrophil cytoplasmic antibody; MPO, myeloperoxidase; p-ANCA, perinuclear antineutrophil cytoplasmic antibody.

Adapted from Sable-Fourtassou R, Cohen P, Mahr A, et al: Antineutrophil cytoplasmic antibodies and the Churg-Strauss syndrome. *Ann Intern Med* 143:632–638, 2005; and Sinico RA, Di Toma L, Maggiore U, et al: Prevalence and clinical significance of antineutrophil cytoplasmic antibodies in Churg-Strauss syndrome. *Arthritis Rheum* 52:2926–2935, 2005.

eosinophilic disease with vasculitis. Diagnostic difficulties thus largely depend on the stage of disease at which the patient is seen. Although systemic disease is necessary to consider a diagnosis of EGPA, it is extremely important that the diagnosis be established before severe organ involvement (especially cardiac) is present.

There are currently no established diagnostic criteria for EGPA. Lanham and associates⁹⁸ have proposed three diagnostic criteria including (1) asthma, (2) eosinophilia exceeding $1.5 \times 10^9/L$ ($1500/\mu L$), and (3) systemic vasculitis of two or more extrapulmonary organs. According to the classification criteria (which are not *diagnostic* criteria, however) of the American College of Rheumatology,¹⁵³ a sensitivity of 85% and a specificity of 99.7% are obtained if four or more of the six following criteria are present in a patient with proven systemic vasculitis: asthma; eosinophilia greater than 10% on differential blood cell count; mono-neuritis (including multiplex) or polyneuropathy; fluctuating opacities on chest radiography; bilateral maxillary sinus abnormalities; or presence of extravascular eosinophils on a biopsy including a vessel. However, these diagnostic and classification criteria were proposed before ANCAs were available. In the future, the presence of ANCA will probably be considered a major diagnostic criterion when present, and provisional diagnostic criteria have been proposed.⁹⁰ A pathologic diagnosis of EGPA is desirable, but not mandatory, in patients with characteristic clinical features and marked eosinophilia. The skin, nerve, and muscle are the most common sites where a pathologic diagnosis of vasculitis may be obtained.⁹⁴ Biopsy of the cutaneous lesions is the most common and simple procedure to obtain pathologic evidence of vasculitis. Lung biopsy is seldom done. Transbronchial biopsies usually do not show vasculitis or granulomata.

Differential Diagnosis

The borders separating EGPA from the other ANCA-associated vasculitides and the other eosinophilic syndromes are sometimes difficult to establish. An overlap between ANCA-negative EGPA and unclassified systemic eosinophilic disease is possible. An eosinophilic variant of granulomatosis with polyangiitis has been described.¹⁵⁵ Concurrent EGPA and pulmonary opacities and temporal arteritis (either with or without giant cells, either eosinophilic or not) have been described.¹⁵⁶ Distinguishing between mild EGPA and ICEP with minor extrathoracic symptoms may also be difficult, especially in the absence of

typical polyangiitis features. Some mild vasculitis (non-necrotizing) is common on pathologic examination of the lung in patients with ICEP.¹⁵ ICEP may further progress to EGPA.⁴⁹ In addition, some cases of “limited” EGPA have been reported,¹⁵⁷ including those solely involving the lung or the heart. *Formes frustes* of EGPA often consist of cases in which the disease has been controlled to a greater or lesser extent by corticosteroids given for asthma. Other cases are difficult to classify as either EGPA or idiopathic HES. Careful clinical analysis, the presence of ANCA, the finding of a vasculitis and granulomas on biopsy, and molecular biologic analysis (in the cases of idiopathic HES) help in determining the final diagnosis.

Interestingly, recent studies have demonstrated that ANCA status may characterize two distinct clinical phenotypes in EGPA^{123,124,158,158a} (Table 68-3). Hence patients *with* ANCA, representing approximately 40% of patients, have a *vasculitic phenotype* of disease with an increased frequency of extracapillary glomerular lesions, peripheral neuropathy, purpura, and biopsy-proven vasculitis. Conversely, EGPA patients *without* ANCA have a *tissue* phenotype of disease with more frequent cardiac and pulmonary involvement (and fever). The latter might conceivably represent a variant of the HES with systemic manifestations.^{123,159} The vasculitic phenotype of EGPA is more frequent in patients carrying the major histopathology complex DRB4 allele.¹³⁷ The ANCA-negative EGPA is associated with the *IL10*-3575/1082/592 TAC haplotype (part of the ancient haplotype IL-10.2 correlated with increased IL-10 expression). Thus genetic predisposition may affect the phenotype of EGPA.

Treatment and Prognosis

Corticosteroids are the mainstay of treatment of EGPA and suffice in a large number of cases.^{98,160,161} Initial methylprednisolone pulses, for 1 to 3 days, are useful in the most severe cases, then oral treatment is started, usually with 1 mg/kg/day of prednisone. Treatment is prolonged for several months with progressive reduction of doses. Relapses are common, and asthma often persists (or reappears if it had disappeared during high-dose corticosteroid treatment). Distinguishing relapse or persistence of so-called difficult asthma from relapse or persistence of EGPA requires precise evaluation, taking into account the levels of blood eosinophils (generally $< 1 \times 10^9$ but $< 1000/\mu L$ in asthma without EGPA relapse) and occasionally new systematic manifestations.

Cyclophosphamide therapy should be added to corticosteroids in patients with manifestations that could result in mortality or severe morbidity.¹⁶² A retrospective study^{160,163} of patients with either polyarteritis nodosa or EGPA identified four factors associated with higher mortality: age older than 65, cardiac symptoms (based on easily detectable clinical parameters), gastrointestinal involvement, and renal insufficiency, whereas ear, nose, and throat symptoms were associated with a lower risk of death.¹⁶³ Cardiomyopathy is the main predictor of mortality in multivariable analysis,¹⁵⁸ especially in cases of heart failure.¹⁶⁴ Older age at diagnosis is also associated with a poor prognosis.^{158,165} The risk of relapse of the vasculitis is higher in patients with ANCA¹⁵⁸ and lower in patients with baseline eosinophils $> 3 \times 10^9/L$ ($>3000/\mu L$).¹⁶⁵

The combination of immunosuppressors with corticosteroids improved disease control, despite associated infections (which could be decreased by using bolus instead of oral cyclophosphamide administration).^{166,167} Mortality was associated with disease severity, and treatment with cytotoxic agents did not prevent relapses.¹⁶⁸ Although the optimal duration of therapy remains to be determined, 12 cyclophosphamide pulses were better able to control the disease than a 6-pulse regimen in patients with EGPA and at least one poor prognosis factor at onset.¹⁶⁹ Corticosteroid treatment alone for EGPA patients without poor prognostic factors at onset is efficient, with about half of the patients achieving complete remission without relapse.¹⁷⁰ Therefore immunosuppressive therapy (most commonly with intravenous pulses of cyclophosphamide) in addition to corticosteroids is warranted in patients with poor prognostic factors at onset and especially heart failure.^{113,165} Maintenance therapy with oral azathioprine or intramuscular methotrexate in addition to corticosteroids may be useful in patients who relapse when taking less than 20 mg/day or more of prednisone.

Subcutaneous interferon- α was successfully used mainly in EGPA patients with severe disease.¹⁷¹ High-dose intravenous immunoglobulins, cyclosporin A, and rituximab¹⁷²⁻¹⁷⁵ have been used successfully in case reports or short series. The anti-IgE omalizumab has been used successfully in patients with EGPA to treat persistent asthma^{176,177}; however, it does not control the systemic disease, and careful clinical monitoring is warranted. Mepolizumab has a glucocorticoid-sparing effect, reduces exacerbations, and improves asthma control in patients with eosinophilic asthma requiring daily oral glucocorticoid therapy.^{177a,177b} Mepolizumab is under evaluation as a potential therapy in EGPA.^{178,179}

The prognosis of EGPA has improved considerably over time,¹⁵⁸ with almost 80% of patients alive at 5 years¹⁶⁰ and 97% alive at 5 years in one recent series of EGPA without poor prognostic factors.¹⁸⁰ Most deaths during the first year of treatment are due to cardiac involvement.¹⁸¹ In one series, EGPA did not appear to confer increased mortality, a rather surprising finding.¹⁰¹ As most patients continue to take oral corticosteroids over the long term, treatment-related side effects cause significant morbidity.¹⁸⁰ In addition, airflow obstruction due to uncontrolled asthma is present despite corticosteroids in many patients during follow-up, and persistent airflow obstruction may develop.^{182,183} Airflow obstruction may not respond to

inhaled bronchodilators but may be partly reversible with increased oral corticosteroid treatment.¹⁸²

HYPEREOSINOPHILIC SYNDROME

The definition of the “idiopathic” *hypereosinophilic syndrome* (HES) proposed by Chusid and coworkers¹⁸⁴ in 1975 included (1) a persistent eosinophilia greater than $1.5 \times 10^9/L$ ($1500/\mu L$) for longer than 6 months, or death before 6 months associated with the signs and symptoms of hyper-eosinophilic disease; (2) a lack of evidence for parasitic, allergic, or other known causes of eosinophilia; and (3) presumptive signs and symptoms of organ involvement, including hepatosplenomegaly, organic heart murmur, congestive heart failure, diffuse or focal central nervous system abnormalities, pulmonary fibrosis, fever, weight loss, or anemia. The 14 cases they reported¹⁸⁴ included 2 patients with “prolonged benign hypereosinophilia,” 3 with eosinophilic leukemia, and 1 with possible EGPA. The later published cases of the idiopathic HES also proved heterogeneous, although patients with typical chronic disease shared some common complications, especially cardiac involvement. The diagnosis of HES is now considered in patients with blood hypereosinophilia ($>1.5 \times 10^9/L$ [$1500/\mu L$]) on at least two occasions in the absence of other etiologies for the eosinophilia.

Pathogenesis

In contrast with common hypereosinophilia, which is usually a reactive nonclonal process (as in parasitic disorders), several studies demonstrated that HES may result from a clonal proliferation of lymphocytes producing eosinophilopoietic chemokines (“lymphocytic variant” of HES), or from the clonal proliferation of the eosinophil cell lineage itself (“myeloproliferative variant” of HES, also referred to as *chronic eosinophilic leukemia*).¹⁸⁵⁻¹⁹⁰ The term *idiopathic* should probably be abandoned in the classification of HES¹⁹¹ and may be appropriate only for the proportion of cases that cannot at present be classified in either category. In such genuinely idiopathic cases, innovative diagnostic tools such as the quantitative assessment of the *Wt1* transcript in peripheral blood may help to differentiate HES from other causes of eosinophilia of determined cause.¹⁹²

The “lymphocytic variant” of HES, which may account for about 30% of patients with HES, results from the production of chemokines (especially IL-5) (which promote the accumulation of eosinophils) by clonal Th2 lymphocytes (as demonstrated by clonal rearrangement of the TCR) bearing an aberrant immunologic phenotype (such as CD3⁺CD4⁺). Lymphocyte phenotyping to detect a phenotypically aberrant T-cell subset by flow cytometry and analysis of the rearrangement of the TCR genes in search of T-cell clonality should be performed on the peripheral blood (and bone marrow). The observation of increased IL-5 expression from cultured T cells can also demonstrate that the observed eosinophilia is caused by an expanded population of T cells.¹⁹³ Serum levels of IgE are elevated as a consequence of IL-4 and IL-13 production by Th2 lymphocytes.^{191,194,195} Serum levels of IL-5 and TARC are increased.¹⁹⁶ Most reported patients were recruited from dermatology clinics and had papules or urticarial plaques infiltrated by lymphocytes and eosinophils (and in some of them, a cutaneous

T-cell lymphoma or the Sezary syndrome was ultimately present). In such cases, the HES may be considered as a premalignant T-cell disorder.^{194,195,197}

The “myeloproliferative variant” of HES (or chronic eosinophilic leukemia), accounting for 20% to 30% of cases, is caused by a constitutively activated tyrosine kinase fusion protein created by fusion of *FIP1L1-PDGFR* as a consequence of an interstitial chromosomal deletion of a region in the long arm of chromosome 4 (q12) not detectable by karyotype analysis.^{198,199} Hepatomegaly, splenomegaly, mucosal ulcerations, severe cardiac manifestations resistant to corticosteroid treatment, anemia, thrombocythemia, increased serum vitamin B₁₂, leukocyte alkaline phosphatase and serum tryptase, and circulating leukocyte precursors are common and suggestive of the diagnosis, whereas cutaneous manifestations are infrequent. A pronounced mastocytosis (lacking *KIT* mutations) is frequent. The diagnosis is confirmed by chromosomal rearrangement analysis and transcript study of the *FIP1L1-PDGFR* fusion gene (or nested polymerase chain reaction analysis), which should be systematically performed in patients with HES. The presence of the *FIP1L1-PDGFR* rearrangement is sufficient for the diagnosis of myeloproliferative HES. Presence of the causative deletion can also be demonstrated using FISH probes to the gene *CHIC2* encompassed in the deleted sequence.¹⁹³ The fusion protein transforms hematopoietic cells and is inhibited by imatinib, a tyrosine kinase inhibitor originally used to treat chronic myelogenous leukemia, other chronic myeloproliferative diseases, and gastrointestinal stromal tumors (also characterized by aberrant constitutively activated tyrosine kinases). Imatinib proved efficient for several months in treating HES in patients refractory to corticosteroids, hydroxyurea, and/or interferon- α . One patient relapsed due to a mutation in *PDGFR* conferring resistance to imatinib (thus demonstrating that the *FIP1L1-PDGFR*- α fusion protein is the target of imatinib). Interestingly, IL-5 overexpression is necessary in mice to induce a condition similar to HES, suggesting that additional mechanisms may cooperate with the *FIP1L1-PDGFR* fusion gene in disease etiology.²⁰⁰

Clinical Features

The pulmonary involvement in patients with eosinophilia of clonal origin has not been studied extensively and especially has not been examined in cases classified according to the previously discussed two variants. However, lung or pleural involvement, although uncommon, has been mentioned in some cases^{194,195,201} in patients with clonal lymphoid proliferations. The following data derived from older studies including cases with the two previously mentioned variants of HES may therefore need reevaluation in the future, and the prevalence of pulmonary involvement might be much lower than previously considered.

The HES is more common in men than in women (9:1), and appears between 20 and 50 years.²⁰² The onset is generally insidious, with eosinophilia discovered incidentally in 12% of the patients.²⁰³ The mean eosinophil count at presentation was $20.1 \times 10^9/L$ (21,000/ μL), with an average highest value of $44.4 \times 10^9/L$ (44,000/ μL) in one series.²⁰⁴ Extremely high values of eosinophilia, in excess of $100 \times 10^9/L$ (100,000/ μL), are found in some patients.¹⁸⁴

The main presenting symptoms are weakness and fatigue (26%), cough (24%), and dyspnea (16%).²⁰³ One quarter of the patients may have asthmatic symptoms.²⁰⁵ Severe coughing attacks were present in 40% of the cases in one series²⁰⁴ with no other mention of bronchopulmonary disease. In another series,²⁰⁶ cough was also the predominant feature, with bronchospasm and pulmonary opacities in 11/40 patients each. Cardiovascular involvement, present in 58% of the patients,²⁰² is a major cause of morbidity and mortality. Fibrotic thickening of the endocardium by collagen-rich connective tissue (endomyocardial fibrosis) is characteristic of cardiac disease in HES,^{203,207} which differs from the cardiac involvement seen in EGPA.¹⁰⁷ Endomyocardial fibrosis is preceded by an initial acute necrotic stage followed by a thrombotic process (eFig. 68-5).²⁰² Cardiac manifestations include dyspnea, congestive heart failure, mitral regurgitation, and cardiomegaly.^{203,206} Echocardiography demonstrates the classic features of HES consisting of mural thrombus, ventricular apical obliteration, and involvement of the posterior mitral leaflet.²⁰⁸ The other manifestations of HES²⁰² include neurologic manifestations (thromboemboli, central nervous system dysfunction, and peripheral neuropathies) and cutaneous manifestations (erythematous pruritic papules and nodules, urticaria, and angioedema).^{202,209}

Imaging

Pulmonary involvement is present in about 40% of patients^{184,203} and includes pleural effusion, pulmonary emboli, and interstitial opacities. Chest CT findings in five patients consisted of small nodules with or without a halo of ground-glass attenuation and focal areas of ground-glass attenuation mainly in the lung periphery.²¹⁰ In another series, pulmonary radiologic manifestations varied but most commonly consisted of patchy ground-glass opacities and consolidation.²⁰⁵ CT findings are therefore poorly specific.³⁶ Some of the observed pulmonary imaging changes may correspond to pulmonary edema resulting from cardiac involvement rather than genuine eosinophilic lung involvement.

Laboratory Studies

Only mild eosinophilia at BAL contrasting with high levels of eosinophilia in the blood has been reported in patients with the HES,^{211,212} suggesting that eosinophilia may be compartmentalized in some patients with HES. Serum levels of mast cell tryptase may be elevated, and dysplastic mast cells may be found in the bone marrow, with some patients meeting minor criteria for systemic mastocytosis.²¹³

Treatment and Prognosis

Imatinib has become the first-line therapy in patients with the myeloproliferative variant of HES, especially (but not exclusively) when the *FIP1L1-PDGFR* fusion protein is present.^{198,199} Response to imatinib is more frequent, yet not restricted to, patients carrying the *FIP1L1-PDGFR*- α fusion protein.²¹⁴ Imatinib can be stopped without relapse in some patients, whereas in others low-dose imatinib is necessary to maintain long-term remission.²¹⁵ Corticosteroids may be used, especially in the “lymphocytic variant” of HES (with response in only about half of the patients).^{206,216} The anti-IL-5 antibody mepolizumab has recently been

shown to be beneficial as a corticosteroid-sparing agent in HES patients negative for the *FIP1L1-PDGFR* fusion gene and requiring 20 to 60 mg/day of prednisone to maintain a stable clinical status and a blood eosinophil count of less than $1 \times 10^9/L$ ($<1000/\mu L$).²¹⁷⁻²¹⁹ Other treatments include chemotherapeutic agents (hydroxyurea, vincristine, etoposide); cyclosporin A^{202,204,216}; and interferon- α either as monotherapy²²⁰⁻²²³ or in association with hydroxyurea, particularly in the myeloproliferative variant.^{224,225}

Whereas the 3-year survival was only 12% in the first published series,¹⁸⁴ the prognosis has improved markedly in later series with about 70% survival at 10 years,²⁰³ 80% survival at 5 years, and 42% at 10 and 15 years, respectively.²⁰⁶ It is fascinating that advances in molecular biology may result in direct clinical benefit and provide a better prognosis for patients with an up-to-now almost untreatable disease.

IDIOPATHIC HYPEREOSINOPHILIC OBLITERATIVE BRONCHIOLITIS

A distinct entity coined *hypereosinophilic obliterative bronchiolitis* has been recently identified¹⁵⁴ and is defined by the following provisional working criteria: (1) blood eosinophil cell count greater than $1 \times 10^9/L$ ($>1000/\mu L$) and/or bronchoalveolar lavage eosinophil count greater than 25%; (2) persistent airflow obstruction despite high-dose inhaled bronchodilators and corticosteroids; and (3) eosinophilic bronchiolitis at lung biopsy and/or direct signs of bronchiolitis (centrilobular nodules and branching opacities) on chest CT (Fig. 68-9).¹⁵⁴ Before this description, biopsy-proven isolated cases of eosinophilic bronchiolitis had been reported.^{226,227,227a} The blood eosinophil cell count is elevated (with a mean of $2.7 \times 10^9/L$ ($2700/\mu L$), and the mean eosinophil differential percentage at BAL was 63% in our series. Airflow obstruction is often severe but reversible with oral corticosteroid therapy in all cases. Whitish tracheal and bronchial granulations or bronchial ulcerative lesions can be present with prominent eosinophilia at bronchial biopsy.¹⁵⁴ Clinical and functional manifestations often recur when oral prednisone is tapered to less than 10 to 15 mg/

day. It is hypothesized that unrecognized and/or smoldering hypereosinophilic obliterative bronchiolitis might be a cause of irreversible airflow obstruction in chronic eosinophilic respiratory diseases. In addition to the idiopathic presentation, a similar condition of hypereosinophilic obliterative bronchiolitis can be encountered in patients with asthma, ABPA, or EGPA or may be induced by drugs, especially minocycline.¹⁵⁴

EOSINOPHILIC LUNG DISEASE OF DETERMINED CAUSE

EOSINOPHILIC PNEUMONIAS OF PARASITIC ORIGIN

The eosinophilic pneumonias related to parasite infestation probably represent the most common cause of eosinophilic pneumonia in the world. Parasitic eosinophilic pneumonia arises mainly in humans following infection by helminths (large multicellular worms) and especially nematodes (roundworms; see eFig. 39-1). The parasites may or may not be found at pathologic examination of the lung when performed (see also Chapter 39).

Tropical Eosinophilia

Clinical Features. Tropical eosinophilia²²⁸ is a syndrome characterized by severe spasmodic bronchitis, leukocytosis, and high blood eosinophilia. The clinical manifestations present mainly in the second and third decades of life, with a male predominance. It has been reported mostly in Indians and occasionally in patients originating from India or Asia and living in North America or in Europe.^{229,230} Tropical pulmonary eosinophilia is one of the most common causes of cough in tropical areas with endemic filariasis.²³¹ Patients develop a dry, hacking cough exacerbated at night (especially between 1 and 5 AM) and often associated with dyspnea and expiratory wheezing. Associated fever, loss of weight, and anorexia are common. Eosinophils, and sometimes Charcot-Leyden crystals, are present in the sputum. The chest radiograph can reveal patchy bilateral opacities and small nodules (see eFig. 39-2A and B, Fig. 39-2A and B).

Pathogenesis. Tropical eosinophilia caused by the filarial nematodes *Wuchereria bancrofti* and *Brugia malayi* is endemic in the tropical and subtropical areas of coastal regions of Asia, the southern and western Pacific, and Africa (less commonly in South and Central America). The adult worms reside in the lymphatic vessels, leading to lymphatic obstruction with subsequent elephantiasis. Humans are infected by infective larvae deposited in the skin by mosquitoes, which develop into mature worms within 6 to 12 months. First-stage larvae or microfilariae released from the fecund female's uterus circulate in the bloodstream from where they are ingested by the mosquitoes.

Patients with tropical pulmonary eosinophilia do not usually have clinical features of lymphatic filariasis. Microfilariae are usually not found in the blood or the lung. The circulating microfilariae are trapped in the lung vasculature where they release their antigenic contents, further triggering the inflammatory pulmonary reaction. The

Figure 68-9 Idiopathic hypereosinophilic bronchiolitis. Axial chest CT scan of a patient with idiopathic hypereosinophilic bronchiolitis shows bronchial wall thickening, peripheral tree-in-bud and branching pattern, and central bronchiectasis with mucoid impaction.

clinical features of tropical pulmonary eosinophilia largely result from an immune response of the host to the parasites.²³²

Although blood eosinophilia is high at the early stage (<2 wk) of pulmonary disease, no prominent eosinophilic infiltration is found in the lung. Eosinophilic pneumonia is seen later (1 to 3 months), with the formation of eosinophilic abscesses and granulomatous lesions characterized by the presence of foreign body giant cells, fibroblasts, and epithelioid cells; prominent eosinophilic infiltration is present at the periphery of the granuloma. Cases left untreated for 5 years or more eventually show pulmonary fibrosis with histiocytic infiltration.

Laboratory Studies. Blood eosinophilia is prominent, with more than $2 \times 10^9/L$ ($>2000/\mu L$) in all cases and up to $60 \times 10^9/L$ ($>60,000/\mu L$) in some cases.²³³ IgE levels are increased. Antifilarial IgG antibodies are increased, as in all patients with filariasis. BAL shows intense alveolitis with a mean percentage of 54% of eosinophils with marked degranulation.²³⁴ High levels of eosinophil-derived neurotoxin are present in the BAL.²³⁵ In patients treated with diethylcarbamazine, BAL eosinophils drop within 2 weeks; blood eosinophils also decrease rapidly upon treatment.²³⁴

Persisting irregular basilar opacities are present in about two thirds of patients after 1 year. A “reticulonodular pattern” on chest CT is present in a majority of patients, with other features consisting of bronchiectasis, air trapping, and mediastinal lymphadenopathy.

Lung function tests show a restrictive ventilatory defect, with a reversible obstructive ventilatory defect and hypoxemia in about a quarter of the patients.^{236,237}

Because microfilariae are not detectable in the blood, the diagnosis is made in patients with residence for several months in an endemic area by the combination of the clinical, epidemiologic, and laboratory features, including blood eosinophilia persisting for weeks with an absolute eosinophil count in the blood greater than $3 \times 10^9/L$ ($3000/\mu L$), IgE levels exceeding 10,000 ng/ μL (4200 IU/mL; normal <100 IU/mL), and markedly increased antifilarial IgG. Diagnosis is further supported by clinical improvement in the weeks following treatment. The diagnostic criteria of tropical pulmonary eosinophilia include cough worse at night; residence in a filarial endemic area; eosinophil count greater than 3300/ μL ; and clinical and hematologic response to diethylcarbamazine.²³⁸

Treatment. Diethylcarbamazine is the only effective drug for tropical pulmonary eosinophilia; corticosteroids in addition to diethylcarbamazine may be beneficial.

Ascaris Pneumonia

Pulmonary opacities with eosinophilia (Löfller syndrome) may develop during the migration of the larvae of the parasite through the lung.

Ascaris lumbricoides is the most common helminth infecting humans, especially children, in the tropical and subtropical areas. Mature females in the human intestine release large numbers of eggs expelled with stools, which may survive for several months or years. The disease is transmitted through food or water contaminated by human feces. The infective larvae formed within eggs develop in the

small intestine, penetrate through the intestinal wall, and migrate via the venous circulation to the lungs, where they break out into the alveoli. They then migrate through the bronchi and trachea, are swallowed, and mature into adult worms in the small intestine.

Pulmonary manifestations develop during larval migration to the lungs. Usually, pulmonary symptoms are mild, with cough and wheezing, transient pulmonary opacities (see eFig. 39-1), and blood eosinophilia. Transient fever is present in the majority of patients, with possible pruritic eruption at the time of respiratory symptoms. Blood eosinophilia may be as high as $22 \times 10^9/L$ ($22,000/\mu L$).²³⁹ Symptoms spontaneously resolve in a few days, whereas blood eosinophilia may remain elevated for several weeks. The diagnosis may be made by finding larvae in the sputum or gastric aspirates but is more usually made by the delayed finding of the worm or ova in the stool within 3 months of the pulmonary manifestations.

Intestinal ascariasis is treated with oral mebendazole, 100 mg twice a day for 3 days, or albendazole, 400 mg once.²⁴⁰

Eosinophilic Pneumonia in Larva Migrans Syndrome

Visceral larva migrans²⁴¹ is a zoonotic infection caused in humans by *Toxocara canis*, a parasite infecting many dogs and other canines. Toxocariasis is found in all temperate and tropical areas of the world. Eggs released by female worms pass in the feces of infected dogs, and the soil of public playgrounds in urban areas is therefore often contaminated with eggs of *Toxocara*. Children playing in contaminated areas may become infected, especially when they practice geophagia. Ingested eggs hatch in the intestine, migrate through the portal circulation, and invade the liver, lung, and other organs. However, in humans, the development of the parasite is blocked at the larval stage.

Visceral larva migrans presents predominantly in children, the majority of whom remain asymptomatic and undiagnosed. When symptomatic, patients present with fever, pulmonary manifestations, seizures, and fatigue. Pulmonary manifestations in about 80% of cases consist of cough, wheezes, and dyspnea; pulmonary opacities on chest radiography are present in approximately half the patients with pulmonary symptoms.²⁴¹ Severe pulmonary involvement, which is seen in about 15% to 20% of cases, may benefit from corticosteroids.²⁴²

Although uncommon in adults, toxocariasis may be severe^{243,244} and necessitate mechanical ventilation. Patients present with fever, dyspnea, and pulmonary opacities on chest radiography. Wheezes or crackles are present at pulmonary auscultation. Blood eosinophilia may be present initially or may develop only in the following days. Eosinophils are increased in the BAL differential cell count.

The diagnosis of toxocariasis is difficult because a positive serodiagnosis may be caused by residual antibodies that do not have any diagnostic significance. IgM antibodies can be found throughout the course of helminthiasis and are not diagnostic of recent infection.²⁴⁵

Visceral larva migrans usually requires only symptomatic treatment, the use of antihelmintics being controversial. Corticosteroids seem beneficial in cases with severe pulmonary involvement.

***Strongyloides stercoralis* Infection**

Strongyloides stercoralis is an intestinal nematode that may cause severe autoinfection in immunocompromised patients. It is widely distributed in the tropics and subtropics. Human infection is acquired through the skin by contact with the soil of beaches or mud. Then larvae pass through the circulation to the lungs, where they break into alveoli, ascend the trachea, are swallowed, and reside in the small intestine where they mature. Females deposit eggs that hatch into larvae that pass with feces. Eosinophilia is usually present in recently infected patients, but it is often absent in disseminated disease.²⁴⁶ *S. stercoralis* infection may persist for years and give rise thereafter to severe disseminated strongyloidiasis, which may affect all organs (hyperinfection syndrome), especially with immunosuppression from any cause.

Löffler syndrome develops when larvae migrate through the lungs after acute infection (see eFig. 68-6A). Peripheral blood eosinophilia, in association with pneumonia, bronchospasm, or bronchitis and abdominal pain or diarrhea, suggests strongyloidiasis in patients living, or having traveled, in endemic areas.

About 20% of hospitalized patients with strongyloidiasis have coexisting chronic lung disease.²⁴⁷ Patients with chronic obstructive pulmonary disease (COPD) or asthma receiving corticosteroids and immunocompromised patients are at risk of hyperinfection syndrome. Eosinophilia may or may not be present. Cough, wheezing, and dyspnea are associated with bilateral patchy opacities. Rhabditiform larvae may be recovered by BAL or bronchial washing^{248,249} or in the sputum.²⁵⁰

Diagnosis of strongyloidiasis depends on the demonstration of larvae in the feces or in sputum and BAL fluid (see Fig. 39-1B-C). Immunodiagnostic assays by ELISA methods may be useful for diagnosis and screening. Because of the risk of hyperinfection syndrome that persists for years, all infected patients are treated when diagnosed (ivermectin 200 µg daily for 2 days and repeated 2 weeks later).

Eosinophilic Pneumonias in Other Parasitic Infections

The dog hookworm *Ancylostoma brasiliense* causing cutaneous helminthiasis (creeping eruption) may produce simple pulmonary eosinophilia in 50% of cases. Pulmonary manifestations develop after the seventh day of cutaneous eruption. The human hookworms *Ancylostoma duodenale* and *Necator americanus* are other possible causes of Löffler syndrome.

In early acute schistosomiasis (due to infection with either *Schistosoma haematobium* or *S. mansoni*), patients may develop transient, multiple, small pulmonary nodules on chest radiography (best seen on chest CT scan) and eosinophilia²⁵¹ (see eFig. 68-6B). In chronic schistosomiasis, embolization of ova in small arteries in the lungs results in granuloma formation, occlusion and remodeling of pulmonary arteries, and further pulmonary hypertension mediated by portopulmonary hypertension.^{252,253} The granuloma comprises lymphocytes, eosinophils, and giant cells. A post-treatment eosinophilic pneumonitis (also called lung shift, verminous pneumonia, and reactionary Löffler-like pneu-

monitis) may develop.²⁵⁴ It could result from parasitic antigen release following treatment.

The filarial parasite of dog *Dirofilaria immitis* (the pulmonary fluke) may occasionally develop into adult worms in the human lungs after inoculation of infective larvae by mosquitoes (eFig. 68-6C). It may manifest by eosinophilic pulmonary opacities on chest imaging studies (see Fig. 39-3).

Other parasites causing rare pulmonary manifestations with eosinophilia include *Paragonimus westermani* (see Fig. 39-4 and eFig. 39-3), *Trichomonas tenax*, *Capillaria aerophila*, and *Clonorchis sinensis* (see eFig. 68-6D).

EOSINOPHILIC PNEUMONIAS OF OTHER INFECTIOUS CAUSES

Pulmonary infection with eosinophilia has been reported with the fungi *Coccidioides immitis* (see eFigs. 37-5 through 37-12), *Bipolaris australiensis*, *Aspergillus niger*, and *Bipolaris spicifera*. BAL eosinophilia has been reported in *Pneumocystis jirovecii* pneumonitis in patients with acquired immunodeficiency syndrome (see eFigs. 90-11 through 90-20). Bacterial or viral pulmonary infection (e.g., tuberculosis, brucellosis, respiratory syncytial virus, influenza infection) may occasionally be a cause of eosinophilic pneumonia.

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS AND RELATED SYNDROMES

Allergic Bronchopulmonary Aspergillosis

ABPA^{254a} is distinct from the other pulmonary manifestations due to the fungus *Aspergillus* such as invasive pulmonary aspergillosis developing in immunocompromised patients, aspergilloma developing in preexistent pulmonary cavities, or *Aspergillus fumigatus*-associated asthma.²⁵⁵ However, ABPA may be associated with chronic necrotizing aspergillosis.²⁵⁶ ABPA is characterized by asthma, eosinophilia, and bronchopulmonary manifestations with bronchiectasis secondary to a complex allergic and immune reaction to the presence of *Aspergillus* colonizing the airways in susceptible hosts who are unable to clear the respiratory epithelium of inhaled fungal spores. ABPA develops in 1% to 2% of adults with previous asthma present for several years (with a prevalence of 1% to 2%) and also in up to 7% to 10%^{257,258} of patients in large series of cystic fibrosis. ABPA may be associated with allergic *Aspergillus* sinusitis,^{259,260} which has been considered as a sinus equivalent of ABPA²⁶⁰⁻²⁶⁵ and results in a syndrome called *sinobronchial allergic aspergillosis*. Recently, cases of ABPA have been reported in patients with COPD^{266,267}; however, this association seems to be exceedingly rare despite impaired mucociliary clearance in COPD.

Pathogenesis. ABPA results from an immune and inflammatory reaction in the bronchi and the surrounding parenchyma in response to antigens from *Aspergillus* growing in mucous plugs in the airways of asthmatics. The immunologic response of the host includes—but is not restricted to—both type I hypersensitivity mediated by IgE antibodies and type III hypersensitivity with the participation of IgG and IgA antibodies and of a Th2 CD4⁺ T cell-mediated

immune response accompanied by sustained IL-17 expression.²⁶⁸ Over time, the associated inflammatory reaction results in damage to the bronchial epithelium, submucosa, and adjacent pulmonary parenchyma.^{269,270}

ABPA may have an environmental (and especially occupational) dimension, as suggested by a study of workers in the bagasse-containing sites in sugar cane mills, where ABPA was diagnosed in 7% of workers who had chronic respiratory problems.²⁷¹

Interestingly, an increased prevalence of heterozygotic *cystic fibrosis transmembrane conductance regulator* (CFTR) gene mutations has been reported in non-cystic fibrosis patients with ABPA or sinobronchial allergic mycosis,^{272,273} suggesting that CFTR gene mutations could be involved in the development of these conditions without overt cystic fibrosis. Genetic susceptibility to develop ABPA has also been suggested by association with a polymorphism within the IL-4 receptor α -chain gene²⁷⁴ and association with HLA-DR subtypes.²⁷⁵ Infection with nontuberculous mycobacteria may be seen with increased frequency in patients with ABPA.²⁷⁶ ABPA has been reported after infliximab therapy for sarcoidosis.²⁷⁷

Diagnostic Criteria. The classical diagnostic criteria include asthma, history of pulmonary opacities, proximal bronchiectasis, elevated serum IgE, and immunologic hypersensitivity to *A. fumigatus* such as immediate reaction to prick test for *Aspergillus* antigen, precipitating antibodies against *A. fumigatus*, and elevated specific IgE against *A. fumigatus*.^{278,279} Other common findings in patients with ABPA include the expectoration of mucous plugs, the presence of *Aspergillus* in sputum, and late skin reactivity to *Aspergillus* antigen.²⁷⁸ In patients with ABPA, typical proximal bronchiectasis may be absent; such cases are designated ABPA seropositive.²⁸⁰ Revised criteria have recently been proposed to account for some of the components that may be more important than others (Table 68-4).²⁸¹ A high index of suspicion should be maintained in patients with

particularly severe asthma, and yet those with negative *Aspergillus fumigatus*-specific IgE are unlikely to have ABPA.²⁸¹

About 40 antigenic components can bind with IgE antibodies, of which 22 recombinant *Aspergillus* allergens (named *Asp f1* to *Asp f22*) are identified.²⁸⁰ Specific antibodies to recombinant *Asp f4* and *Asp f6* may be the most helpful for diagnostic purposes.²⁸²

Five stages of ABPA have been distinguished: acute, remission, recurrent exacerbations, corticosteroid-dependent asthma, and fibrotic end stage. However, a newly proposed staging system merits evaluation.²⁸¹ Pulmonary opacities or peripheral blood eosinophilia may be present only during the acute phase or recurrent exacerbations of the disease.

Imaging. Damage to the large bronchi is a major feature of ABPA, with mucous plugs containing *Aspergillus* obstructing the airways with subsequent atelectasis and bronchial wall damage. Proximal bronchiectasis (in the medial half of the lung from the hilum to the chest wall) predominates in the upper lobes and is well visualized on chest CT.²⁸³⁻²⁸⁶ However, proximal bronchiectasis (see Fig. 48-10) lacks both sensitivity and specificity and further represents a complication of ABPA and not a diagnostic criterion of early disease.²⁸¹ Muroid impaction of high attenuation, mosaic attenuation, centrilobular nodules, and tree-in-bud opacities are also commonly seen (see Figs. 48-3 and 48-11). In asthmatic patients, the presence of bronchiectasis affecting three or more lobes, centrilobular nodules, and muroid impaction on CT scan is highly suggestive of ABPA (Fig. 68-10)²⁸⁷; because of its characteristic imaging presentation, the correct diagnosis of ABPA was made on CT scan in 84% of cases of ABPA in a series of patients with eosinophilic lung diseases.³⁶ The CT imaging pattern may be classified as serologic ABPA (without bronchiectasis), ABPA with bronchiectasis, ABPA with high-attenuation mucus, and ABPA with pleuropulmonary

Table 68-4 Newly Proposed Diagnostic Criteria for Allergic Bronchopulmonary Aspergillosis

Predisposing conditions	<ul style="list-style-type: none"> ■ Bronchial asthma ■ Cystic fibrosis
Obligatory criteria (both should be present)	<ul style="list-style-type: none"> ■ Type I <i>Aspergillus</i> skin test positive (immediate cutaneous hypersensitivity to <i>Aspergillus</i> antigen) or elevated IgE levels against <i>Aspergillus fumigatus</i> ■ Elevated total IgE levels (>1000 IU/mL)*
Other criteria (at least 2 of 3)	<ul style="list-style-type: none"> ■ Presence of precipitating or IgG antibodies against <i>A. fumigatus</i> in serum ■ Radiographic pulmonary opacities consistent with ABPA† ■ Total eosinophil count >500 cells/μL in steroid-naïve patients (may be historical)

*If the patient meets all other criteria, an IgE value < 1000 IU/mL may be acceptable.

†The chest radiographic features consistent with ABPA may be transient (i.e., consolidation, nodules, tram-track opacities, toothpaste/finger-in-glove opacities, fleeting opacities) or permanent (i.e., parallel line and ring shadows, bronchiectasis and pleuropulmonary fibrosis).

From Agarwal R, Chakrabarti A, Shah A, et al: Allergic bronchopulmonary aspergillosis: review of literature and proposal of new diagnostic and classification criteria. *Clin Exp Allergy* 43:850–873, 2013.

Figure 68-10 Allergic bronchopulmonary aspergillosis. Axial CT scan of a patient with allergic bronchopulmonary aspergillosis shows central bronchiectasis with mucoid impaction (arrows). Diffuse bilateral inhomogeneous lung opacity is present, with areas of low attenuation throughout the pulmonary parenchyma (arrowheads) representing mosaic perfusion resulting from a combination of large and small airway inflammation.

fibrosis.²⁸¹ In a series of patients with serologic ABPA, central bronchiectasis did not develop during follow-up,²⁸⁸ suggesting that it may correspond to a variant rather than an early stage of disease. Although surgery is seldom warranted, eosinophilic pneumonia may be found in resection specimens from patients with asthma and ABPA with chronic pulmonary consolidation.^{283,289}

The initial stage of ABPA is characterized on imaging by either fleeting opacities due to eosinophilic pneumonia or mucus plugging with ensuing segmental, lobar, or even whole-lung atelectasis. Fever is present. Blood eosinophilia is generally greater than $1 \times 10^9/L$ ($>1000/\mu L$). Sputum and expectorated plugs contain eosinophils and Charcot-Leyden crystals. Serum levels of TARC are elevated and might be used as a marker for identification and monitoring of ABPA.^{290,291} Mucoid bronchial impaction is typically characterized by a V-shaped lesion with the vertex pointing toward the hilum and atelectasis.²⁹² The diagnosis is rarely made at the early acute stage.

Treatment. Management decisions in ABPA are generally based on low-level evidence. In addition to conventional treatment of severe asthma (i.e., high-dose inhaled corticosteroids and long-acting bronchodilators), the treatment of ABPA mainly relies on corticosteroids during exacerbations, with long-term corticosteroids maintained only in patients with frequent symptomatic attacks or evidence of progressive lung damage. Treatment of episodes of pulmonary consolidation may prevent the progression of ABPA to the fibrotic end stage.²⁹³ Inhaled corticosteroids may reduce the need for long-term oral corticosteroids. Oral itraconazole is a useful adjunct to corticosteroids, allowing reduction of the doses of corticosteroids.^{294,295} A double-blind, randomized, placebo-controlled 16-week study indicated that patients with corticosteroid-dependent ABPA generally benefit from concurrent itraconazole treatment; improvements included the immunologic and physiologic criteria and the corticosteroid dose, but there was no significant effect on pulmonary opacities.²⁹⁶ Another randomized study with itraconazole demonstrated that subjects receiving itraconazole had a decrease in sputum eosinophils, sputum eosinophil cationic protein levels, serum IgE levels, and serum IgG levels to *A. fumigatus* and had fewer exacerbations than patients receiving placebo.²⁹⁷ Uncontrolled studies further suggest that itraconazole is potentially useful in ABPA patients with cystic fibrosis.^{298,299} On the basis of these data, the use of itraconazole may be effective in approximately 60% of ABPA patients with asthma²⁹⁹ and is recommended.³⁰⁰ Duration of itraconazole therapy is not standardized; however, treatment is generally continued for a minimum of 4 to 6 months. Itraconazole interacts with many medications and may further induce adrenal insufficiency^{301,302}; oral prednisone and inhaled beclomethasone or ciclesonide should be preferred to oral methylprednisolone and budesonide or fluticasone to reduce interactions.²⁹⁹ Measuring total serum IgE level may be helpful for monitoring therapy. Clinical and radiologic improvement along with a 25% or greater decline in serum total IgE level signifies satisfactory response to therapy.²⁸¹

Treatment with an anti-IgE recombinant antibody omalizumab may be useful in some cases³⁰³⁻³⁰⁵ and in short series,^{306,307} with possibly fewer episodes of exacerbation

and reduction of steroid dose. The appropriate dosing, however, is unknown in the setting of ABPA with IgE levels that exceed 1000 IU/mL. Pulses of intravenous corticosteroids have also been used to treat exacerbations. The newer agents voriconazole and posaconazole have been successfully used in ABPA only in isolated case reports, especially in cystic fibrosis but with no proven benefit as compared with itraconazole.³⁰⁸⁻³¹⁰ Sustained improvement has been reported following administration of nebulized liposomal amphotericin B in patients with ABPA that was difficult to control using the standard treatment regimen.^{311,312}

Other Allergic Bronchopulmonary Syndromes Associated with Fungi or Yeasts

A similar syndrome of allergic bronchopulmonary disease may be produced by other fungi or yeasts.^{313,313a} The frequency of this condition is far less than that of ABPA. The diagnosis is difficult due to the necessity to document for sensitization to the specific fungi.

Bronchocentric Granulomatosis

Bronchocentric granulomatosis³¹⁴ has been described as an inflammatory and destructive process beginning within the bronchiolar walls and further extending into the surrounding parenchyma with a peribronchiolar distribution of the lesions.³¹⁵ The granulomatous inflammatory process destroys both the mucosa and the walls of the bronchioles, and the necrotic areas resulting from the destroyed bronchioles are often surrounded by palisading histiocytes. Scattered fungal hyphae may be demonstrated by the Grocott silver stain in some patients. A dense inflammatory infiltrate is, in most cases, present in the peribronchial tissue. In asthmatic patients with bronchocentric granulomatosis, eosinophils compose the major proportion of the infiltrate. Other possible changes include vascular inflammation and mucoid impaction.^{315,316}

About half the patients with bronchocentric granulomatosis at lung pathologic examination are asthmatics who further present with fever and cough. A peripheral blood eosinophilia is common, generally greater than $1 \times 10^9/L$ ($>1000/\mu L$).^{315,316} The radiographic features consist of masses (eFig. 68-7), alveolar opacities or pneumonic consolidation, or reticulonodular opacities, which predominate in the upper lobes and are unilateral in a majority of patients.^{317,318} Most of these patients fulfill the criteria for ABPA, and those treated with corticosteroids have an excellent prognosis, although recurrences are common.³¹⁵ Eosinophilia is usually not conspicuous when bronchocentric granulomatosis develops in patients without asthma (an infectious cause is found in some cases).

DRUG-, TOXIC AGENT-, AND RADIATION-INDUCED EOSINOPHILIC PNEUMONIAS

DRUGS

More than 80 drugs have been reported to cause eosinophilic pulmonary opacities and especially acute eosinophilic pneumonia (Table 68-5). However, the causality has not been established in many case reports and thus the number

Table 68-5 Drugs That May Cause Acute Eosinophilic Pneumonia

Ampicillin	Mefenamic acid
Cannabis	Minocycline
Chloroquine	Nomifensine
Cocaine (snorted)	Progesterone
Daptomycin	Pyrimethamine-sulfadoxine
Ethambutol	Risperidone
Excipients and vehicle	Sertraline
Fludarabine	Tacrolimus
Fluoxetine	Tobacco smoking, cigarette smoke
Gemcitabine	Tryptophan
Heroin	Venlafaxine
Infliximab	

Data from www.pneumotox.com.

of drugs that can reliably be considered as a common cause of drug-induced eosinophilic pneumonia is much smaller. Drugs causing eosinophilic pneumonia are mainly nonsteroidal anti-inflammatory drugs and antibiotics. The online database www.pneumotox.com is a reliable reference in the evaluation of suspected cases, providing a list of causative drugs for which eosinophilic lung disease has been published.

Drug-induced eosinophilic lung disease may present in three main clinical settings: (1) patients taking a drug for several months (or years) for the treatment of chronic disease who progressively develop increasing dyspnea with cough and mild fever; (2) asymptomatic patients who are found to have an interstitial lung disease by routine chest radiography; (3) patients who present with acute eosinophilic pneumonia sometimes requiring mechanical ventilation. Associated extrapulmonary iatrogenic manifestations, especially cutaneous rashes, fever, or nausea, may be present. Severe cases may present as *drug reaction with eosinophilia and systemic symptoms* (DRESS).^{319,320}

All the drugs taken in the weeks or months preceding the clinical syndrome must be carefully recorded in any patient presenting with eosinophilic pneumonia, including illicit drugs (cocaine, heroin), the intake of which is often denied by the patient.

Simple pulmonary eosinophilia also called Löffler syndrome (with transient pulmonary opacities), chronic eosinophilic pneumonia, and acute eosinophilic pneumonia have all been reported as drug-induced syndromes. Systemic eosinophilic vasculitis involving the lung (and thus closely resembling EGPA) has also been reported.^{141,321}

The regression of eosinophilic lung disease after stopping the drug is the best clue for an iatrogenic reaction. However, this may take a long time and, therefore, in many reported cases, corticosteroids have been given concomitantly with drug withdrawal, so the responsibility of the drug cannot be definitely established. The only absolute proof of the drug responsibility would be obtained by its reintroduction with ensuing relapse of pneumonia, but this may be dangerous and thus unethical if done only for scientific purposes. Careful reintroduction of a drug presumed to be the cause of eosinophilic pneumonia may be considered with careful monitoring only when no alternative treatment for a serious disease is available.

Presentation of eosinophilic drug-induced pneumonia is generally nonspecific. Although, in most cases, patients present with pulmonary manifestations compatible with

ICEP (with the exception of possible associated pleural effusion and extrapulmonary manifestations including cutaneous rash), other patients present with features characteristic of IAEP. Therefore, in any case of “idiopathic” eosinophilic pneumonia, an iatrogenic cause must be systematically considered.

The eosinophilia-myalgia syndrome, which developed in 1989 in the United States, was related to the intake of contaminated preparations of L-tryptophan. It manifested with frequent dyspnea and cough, myalgia, fatigue, rash, paresthesia, swelling, and muscle weakness, with interstitial lung disease or opacities on chest CT in 13% of cases,³²² and peripheral blood eosinophilia. The outcome was favorable, especially in patients receiving corticosteroids.³²²⁻³²⁴ A new case has been reported recently after the sale of L-tryptophan has been authorized again.³²⁵

Ingestion of denatured cooking oil was the cause of the toxic oil syndrome, which affected about 20,000 people in Spain in 1981.³²⁶ This scleroderma-like disorder was characterized by an interstitial-alveolar pattern on chest imaging and eosinophilia during the first 4 months.

RADIATION THERAPY

Chronic eosinophilic pneumonia may develop after radiation therapy for breast cancer.^{327,328} It was seen in women with a history of asthma or allergy, at a median time of 3.5 months and up to 10 months after completion of radiotherapy for breast cancer (one case has been reported six years after completion of radiation therapy).³²⁹ Dyspnea and cough were the main presenting symptoms, with pulmonary opacities at imaging being unilateral (involving the irradiated lung) or bilateral, and possibly migratory. All patients had blood eosinophilia of $1.0 \times 10^9/L$ (1000/ μL) or greater and/or eosinophilia greater than 40% on the BAL differential cell count. Patients rapidly improved with oral corticosteroids without sequelae, but some patients relapsed after treatment withdrawal. This syndrome is similar to the organizing pneumonia syndrome primed by radiation therapy to the breast,³³⁰ with eosinophilic pneumonia developing preferentially in patients with asthma or atopy. Eosinophilic pneumonia may also develop on radiation therapy preferentially in patients with a preexisting Th2-oriented lymphocyte response,^{327,331,332} together with yet unidentified additional factors.

MISCELLANEOUS LUNG DISEASES WITH ASSOCIATED EOSINOPHILIA

Eosinophilia in blood and/or in BAL has been reported in some pulmonary disorders in which eosinophilic pneumonia is not a major finding.

ORGANIZING PNEUMONIA

Organizing pneumonia is defined by the presence of buds composed of inflammatory cells, fibroblasts, and connective tissue within the lumen of distal air spaces. It may be secondary to various causes (such as infection or drug-induced reactions) or be cryptogenic. The typical clinical and

imaging features (patchy alveolar opacities) of organizing pneumonia may closely mimic ICEP.³³³ Furthermore, pathologic overlap of organizing pneumonia and ICEP may be encountered, with foci of organizing pneumonia in ICEP, and eosinophils in organizing pneumonia. In some cases, organizing pneumonia may represent the evolution of an untreated CEP.³³³ Eosinophilia in BAL may be present in cryptogenic organizing pneumonia, but it is usually less than 20% at differential cell count.

ASTHMA AND EOSINOPHILIC BRONCHITIS

Infiltration of the airways by eosinophils is common in the eosinophilic pneumonias but may also be an isolated phenomenon. The eosinophil is considered to play a major role in the pathogenesis of asthma.³³⁴ Eosinophilic inflammation of the airways present in the submucosa and epithelium of patients with asthma is correlated with severity of asthma.³³⁵ BAL has shown mildly increased levels of eosinophils (usually <5%) on differential cell count in asthmatics, with the increase in eosinophils in the alveolar samples less than in bronchial samples.³³⁶ Interestingly, although eosinophilic infiltration of the bronchi is common in the eosinophilic pneumonias, asthma is not a constant feature in such disorders. The eosinophilic phenotype of asthma has recently been the focus of particular attention because substantial eosinophilic airway inflammation (often with little or no increase in the peripheral blood eosinophil numbers) is a marker of steroid-responsive disease, is associated with a high risk of exacerbations, and may be targeted by specific inhibitors, including the anti-IL-5 humanized monoclonal antibodies mepolizumab and reslizumab, and a monoclonal antibody to the IL-5 receptor (IL5RA) benralizumab.³³⁷ Furthermore, some patients present with asthma and important blood hypereosinophilia (i.e., >1 and especially $>1.5 \times 10^{-9}/L$ (1500/ μL) or alveolar eosinophilia (>25% and especially >40%), a condition tentatively labeled “hypereosinophilic asthma.”^{338,339} Hypereosinophilic asthma is generally severe, frequently requires high-dose inhaled or even oral corticosteroids, and may progress to EGPA, ABPA, or ICEP.

Eosinophilic bronchitis (without asthma) with a high percentage of eosinophils (about 40%) in sputum is a cause of chronic cough responsive to corticosteroid treatment,³⁴⁰ with normal lung function and absence of bronchial hyperactivity.^{341,342} It is not accompanied by eosinophilic pneumonia. The observed values of sputum eosinophils are often much higher in eosinophilic bronchitis than in asthma.³⁴² The *FIP1L1-PDGFR* fusion gene has been reported in one patient with eosinophilic bronchitis.³⁴³ Treatment is based on inhaled corticosteroids.^{340,344} Treatment with an antagonist of the eotaxin tissue receptor CCR3, the receptor for eotaxin and other chemokines, may be beneficial.³⁴⁵ Eosinophilic bronchitis is distinct from bronchial asthma, although it may in rare cases evolve over time to irreversible airflow obstruction without asthma or to genuine asthma.^{346,347}

IDIOPATHIC INTERSTITIAL PNEUMONIAS

Mildly increased levels of eosinophils may be found in the BAL differential cell count in the idiopathic interstitial pneumonias (idiopathic pulmonary fibrosis, nonspecific

interstitial pneumonia, cryptogenic organizing pneumonia, desquamative interstitial pneumonia). Increase of BAL eosinophils is associated with a poor outcome.³⁴⁸⁻³⁵⁰ Focal eosinophilic pneumonia has been reported in cases of usual interstitial pneumonia,³⁵¹ and focal findings of eosinophils are a minor feature of nonspecific interstitial pneumonia.³⁵²

LANGERHANS CELL HISTIOCYTOSIS

Pulmonary Langerhans cell histiocytosis (also designated as eosinophilic granuloma or pulmonary histiocytosis X) results from the proliferation of Langerhans cells. The pulmonary pathologic lesions consisting of nodules often assuming a bronchiolocentric stellate shape are composed of Langerhans cells with variable numbers of eosinophils, plasma cells, and lymphocytes. Eosinophils usually present in the initial active stage of disease contribute to the “eosinophilic granuloma.” Numerous in about 25% of cases, they are usually situated at the periphery of the lesions. The eosinophils are rare or absent at the chronic stage of disease.

LUNG TRANSPLANTATION

Eosinophilic alveolitis in lung transplant recipients may be indicative of acute rejection (tissue eosinophilia is involved in rejection after renal, cardiac, hepatic, and pancreatic transplantation). BAL eosinophilia of 2% or greater is associated with a poor outcome in lung transplantation.³⁵³ However, pulmonary eosinophilia in lung transplant recipients may also result from infectious agents such as *Aspergillus*, *Pseudomonas*, or coxsackievirus.³⁵⁴

OTHER LUNG DISEASES WITH OCCASIONAL EOSINOPHILIA

Blood eosinophilia and tissue eosinophilia may be present in sarcoidosis but are usually mild.³⁵⁵ Pulmonary eosinophilia developed in two patients after transplantation for sarcoidosis, with bronchiolitis obliterans syndrome developing after resolution of pulmonary eosinophilia.³⁵⁶ Eosinophilic pneumonia was reported in a patient with gastric cancer producing GM-CSF and IL-5.³⁵⁷

Key Points

- Eosinophilic lung disease may manifest clinically with varying severity, ranging from chronic or transient opacities with mild symptoms to the acute severe eosinophilic pneumonia resembling acute lung injury or acute respiratory distress syndrome and necessitating mechanical ventilation.
- Blood eosinophilia greater than 1×10^9 eosinophils/L (and preferably $>1.5 \times 10^9/L$ or 1500/ μL) is of considerable help for suggesting the diagnosis. However, blood eosinophilia may be absent (as in the early phase of idiopathic acute eosinophilic pneumonia or when patients are already taking corticosteroids).
- On bronchoalveolar lavage, high eosinophilia (>25%, and preferably >40%) may be considered diagnostic of eosinophilic pneumonia in a compatible setting.

- Inquiry concerning drug intake must be meticulous (www.pneumotox.com), and any suspected drug should be withdrawn.
- Consideration of parasitic causes must take into account the travel history or residence and the epidemiology of parasites.
- When present, extrathoracic manifestations raise the suspicion of a systemic eosinophilic disease such as *eosinophilic granulomatosis with polyangiitis* (Churg-Strauss syndrome) (EGPA) or *hypereosinophilic syndrome* (HES), whereas airflow obstruction can be found in hypereosinophilic asthma, allergic bronchopulmonary aspergillosis, idiopathic chronic eosinophilic pneumonia, EGPA, or in the recently identified syndrome of hypereosinophilic obliterative bronchiolitis.
- Corticosteroids remain the cornerstone of symptomatic treatment for eosinophilic disorders, with a generally dramatic response, but relapses are common when tapering the doses or after stopping treatment. Cyclophosphamide is necessary in patients with EGPA and poor prognostic factors.
- Imatinib has proved effective in the treatment of the myeloproliferative variant of HES.

INTRODUCTION

Lymphangioleiomyomatosis (LAM) is a rare neoplastic disease characterized by a genetic association with the neurocutaneous syndrome, *tuberous sclerosis complex* (TSC), marked female gender predominance, cystic destruction of the lung, and progressive respiratory failure. Symptoms and signs include dyspnea on exertion, recurrent pneumothorax, abdominal tumors including renal *angiomyolipomas* (AMLs) and lymphangiomyomas, and chylous fluid accumulation in the chest and abdomen.^{1,2}

LAM was first reported in a patient with TSC who presented with bilateral spontaneous pneumothorax in 1918³ and in a patient without TSC in 1937.⁴ In the 1950s through the late 1960s, there were solitary case reports or small case series that fostered a varied and confusing pathologic nomenclature in the literature. Cornog and Enterline,⁵ for example, described six cases of “lymphangioleiomyoma” in 1966 and reviewed 14 prior cases in the literature with similar pathology that had been termed “lymphangioma,” “lymphangiomyoma,” “lymphangiopericytoma,” “leiomyomatosis,” “lymphangiomatosis malformation,” and “intrathoracic angiomatous hyperplasia.” Since the late 1970s, larger case studies have better defined the natural history, pathologic classification, and clinical presentation of LAM.^{6–14} Moreover, in the past 2 decades, synergistic interactions between pulmonary investigators, tuberous sclerosis geneticists, *Drosophila* biologists, and patient advocacy groups have resulted in truly remarkable progress in our understanding of the molecular and cellular basis of LAM,¹⁵ as well as the development of a targeted therapy.

EPIDEMIOLOGY

LAM is seen both in the setting of *tuberous sclerosis complex* (TSC-LAM) and in a sporadic form in patients who do not have germline mutations in TSC genes or the clinical syndrome of TSC (sporadic LAM, or S-LAM) (Table 69-1).^{1,2}

TSC is an autosomal dominant genetic disorder associated with development of hamartomas and dysplastic lesions in several organs, including cortical tubers, giant cell astrocytomas, and subependymal nodules in the central nervous system; angiofibromas, shagreen patches, and ash leaf macules of the skin; and AMLs and cysts of the kidney.¹⁶ The cystic lung changes seen in patients with TSC are typically presumed to be due to LAM but, because the lung is not routinely biopsied in this population, other etiologies are also possible. There have been a number of case reports of biopsy-proven LAM in women with TSC, as well as in a few in men with TSC.^{17–19} In cross-sectional studies from tertiary referral centers, TSC-LAM has been reported in about 10% of men and 30% of women with TSC^{20–22}; although a recent screening study suggested that age-dependent development of cystic change in women with TSC results in an estimated LAM prevalence of up to 80% by age 40.²³ Symptomatic TSC-LAM is almost entirely restricted to women. In S-LAM, in contrast, lesions of the skin and brain are absent, and manifestations that accompany the pulmonary cystic changes include only renal and extrarenal AMLs and smooth muscle infiltration and obstruction of the lymphatic system. A clinical presentation consistent with S-LAM, including biopsy documentation and negative germ line TSC mutation analysis, has been reported in a single male without clinical evidence of TSC.²⁴

Careful epidemiologic analyses of the ethnic and racial distribution of LAM have not been performed. Although the biases introduced by the rarity of the illness, the protean presentation, and the disproportionate reporting of patients with LAM in large series from the United States, Europe, and Asia^{9–12,14} might suggest a predilection of the disease for whites and Asians, it is likely that all races are affected and that countries and populations with the greatest access to health care resources are overrepresented in these studies.

Harknett and colleagues²⁵ determined that LAM was diagnosed in 3.4 to 7.8 women per million across seven

Table 69-1 Comparison of TSC-LAM and S-LAM

	TSC-LAM	S-LAM
Estimated no. patients worldwide	150,000	10,000-30,000
Reported in males	+	+(one)
Reported in children	+	+
Ascertainment	Screening, dyspnea, pneumothorax	Dyspnea, pneumothorax, chylothorax, incidentally on CT
Germline TSC mutations	+	—
Inheritable	+	—
TSC1/TSC2 mutations reported	33%/66%	0%/100%
Renal angiomyolipomas	93% Bilateral 81% Multiple 60%	33% Bilateral 19% Multiple 6%
Hepatic angiomyolipomas	33%	2%
Lymphangiomyomas	9%	29%
MMPH	+ (~12%)	Very rare, if ever (~1%)
CNS/skin/eye/cardiac lesions	+	—
Retroperitoneal, thoracic adenopathy	Rare	+
Dyspnea	Less common	More common
Chylothorax	Uncommon	33%
Pneumothorax	Less common	66%
Respiratory failure	Less common	More common

CNS, central nervous system; CT, computed tomography; LAM, lymphangiomyomatosis; MMPH, multifocal micronodular pneumocyte hyperplasia; S-LAM, sporadic lymphangiomyomatosis; TSC, tuberous sclerosis complex.

different countries.²⁵ The authors did not stratify patients by the presence or absence of TSC, but it is likely that both S-LAM and TSC-LAM populations were included in the estimate. Extrapolation of this prevalence range to the 3.4 billion women on earth results in a predicted global LAM population ranging from 11,600 to 26,500 diagnosed patients.

LAM often presents in a protean manner and it is likely that the disease is severalfold more common than these numbers suggest. Considering that the live birth prevalence of TSC is estimated to be 1/10,000 to 1/12,500 persons and that TSC affects both genders equally,²⁶ the estimated worldwide prevalence of TSC is approximately 1.1 million to 1.5 million people (assuming a world population of 7 billion people), with roughly half of them being women. If one estimates that cystic pulmonary changes consistent with LAM are found in one third of women with TSC,²⁰⁻²² the global prevalence of TSC-LAM is about 150,000 to 200,000 women, or upwards of 60 TSC-LAM cases per million women in the general population.

Although screening of TSC populations identifies a subset of LAM patients who have a range of cystic change in the lung from very mild to severe, the degree of cystic profusion is often mild or moderate,²³ and pulmonary manifestations appear to reach clinical significance in only about 5% to 10% of patients with TSC-LAM.²⁷ TSC-LAM is certainly

underrepresented in large trials, registries, and databases: patients with TSC-LAM made up only about 14.7% of the 230 patients who enrolled in the *National Heart, Lung, and Blood Institute* (NHLBI) LAM Registry²⁸ and 9.5% of patients who are listed in the LAM Foundation database (Sally Lamb, personal communication, The LAM Foundation, Cincinnati). Although TSC-LAM is predicted to be 10-fold more common than S-LAM, most patients with LAM (85% to 90%) who seek medical attention with adult pulmonary specialists have S-LAM. This observation is consistent with the notion that TSC-LAM identified through screening is often a milder disease than S-LAM, which typically reaches attention through progressive dyspnea or pneumothorax/chylothorax. It is also possible that other TSC comorbidities may overshadow the pulmonary manifestations of TSC-LAM and hinder TSC-afflicted patients from seeking medical care for their lung disease.

GENETIC AND MOLECULAR BASIS OF TUBEROUS SCLEROSIS COMPLEX AND LYMPHANGIOLEIOMYOMATOSIS

INHERITANCE

Approximately two thirds of new TSC cases arise from de novo mutations, which happen during embryogenesis. Familial TSC, which results from inheritance of germline mutations, accounts for one third of new cases.²⁹ There have been several reports of familial TSC-LAM,^{20,30} but mother-daughter transmission of S-LAM has never been reported.

MOLECULAR PATHOGENESIS

Our understanding of the genetic and molecular basis of TSC and LAM has increased substantially since the late 1990s. The most significant findings have included that LAM is a neoplastic and metastatic process, that LAM is caused by mutations in TSC genes,³¹ and that dysregulation of the Akt signaling pathway plays a central role in LAM cell growth, motility, and survival.^{32,33}

Tumor Suppressor Proteins Control Cell Growth

Clinicians have long recognized that the cystic lung disease in women with TSC is pathologically indistinguishable from that in women with S-LAM.^{5,34} However, the demonstration that S-LAM and TSC-LAM are genetically linked was reported only relatively recently.³⁵ The lag period in our understanding may have been due, in part, to the failure to appreciate that a nonfamilial disease could share a common genetic basis with a heritable disease. There are several precedents for this phenomenon among the class of diseases known as tumor suppressor syndromes (including neurofibromatosis and von Hippel-Lindau syndrome), of which TSC is a member.

Tumor suppressor proteins regulate orderly cell growth and differentiation by sensing the surrounding environment, transmitting signals to the nucleus, and directly affecting transcription, translation, survival, or cell division.

In the classic “two-hit” paradigm,³⁶ a mutant copy of a tumor suppressor gene is inherited from one parent and a tumor or dysplastic lesion develops when the second “good” parental copy of the tumor suppressor gene is inactivated through a random, somatic mutation. This first (inherited) hit, often a point mutation or a small insertion or deletion, results in heterozygosity for the allele (i.e., one good copy and one mutant copy). The second mutational event is usually a large deletion, resulting in the loss of a chromosomal segment and *loss of heterozygosity* (LOH) (two mutant copies). A *polymerase chain reaction* (PCR) technique can be used to detect LOH for the allele caused by the deletion. When both copies of a tumor suppressor gene contain critical mutations, the protein produced by the gene becomes defective or deficient, protein function is lost, and cell growth, survival, and synthetic function become dysregulated.

The Tuberous Sclerosis Complex Proteins Regulate Signaling through the Akt Pathway

TSC is caused by inactivating mutations in either of the two known TSC loci, *TSC1* on chromosome 9q34³⁷ or *TSC2* on chromosome 16p13.³⁸ The proteins encoded by *TSC1* and *TSC2* are hamartin and tuberlin, respectively (Fig. 69-1).

More information on Akt pathway signaling is available online at *ExpertConsult*.

Genetic mutations that result in the absence or dysfunction of tuberlin or hamartin, such as is seen in patients with tuberous sclerosis and LAM, ultimately cause constitutive activation (phosphorylation) of S6 and eIF4E, two proteins that are intimately involved in the regulation of protein translation, as well as Rho kinase, which regulates intracellular trafficking, cell adhesion, and cell movement. The end result is the inappropriate stimulation of protein synthesis, cell motility, and cell growth.³³ Multiple mTOR effectors and mTOR itself were found to be highly phosphorylated in tumors of rats,⁴⁶ mice,⁴⁷ and humans⁴⁸ with mutations in TSC genes. Sirolimus, a microbial product that inhibits mTOR activity, extinguishes phosphoS6 staining and causes widespread apoptosis in the rat renal tumors.⁴⁶

Tuberous Sclerosis Complex Mutations Are Found in the Lung and Kidney Lesions of Patients with Sporadic Lymphangioleiomyomatosis

Tuberous sclerosis patients have germline mutations in TSC genes, but patients with S-LAM do not.⁴⁹ Smolarek and coworkers⁵⁰ first implicated TSC genes in the pathogenesis of S-LAM by finding that LOH for *TSC2* was present in the renal AMLs and lymph nodes of patients with S-LAM. Proof that the loss of tuberlin function was responsible for lung disease in LAM was provided by Carsillo and colleagues, who demonstrated the presence of missense and protein

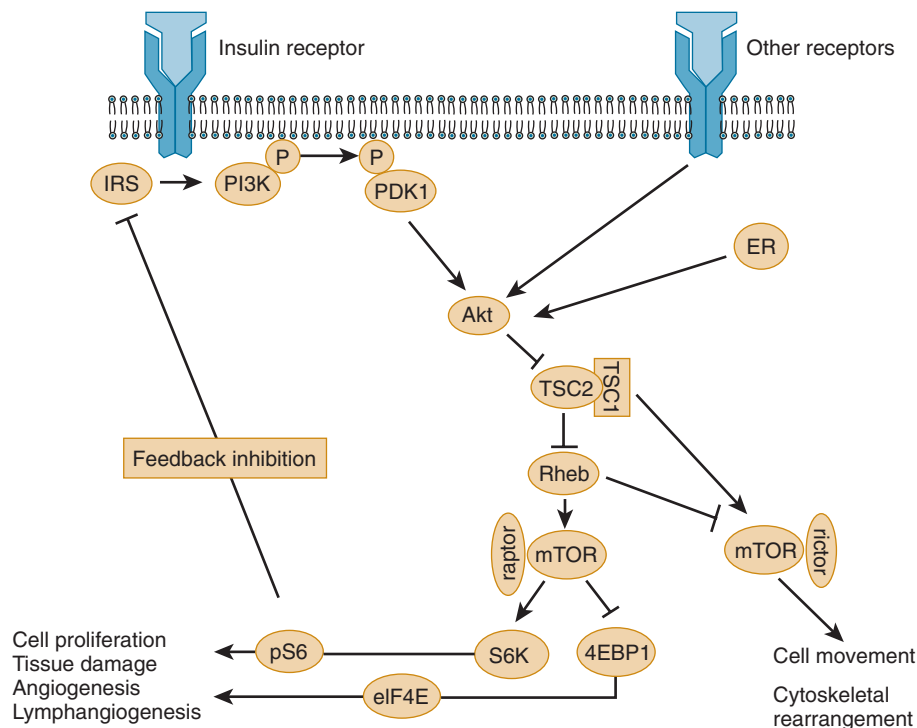

Figure 69-1 Tuberous sclerosis proteins regulate signaling through the Akt growth and protein translation pathway. The binding of a ligand to a growth factor receptor (e.g., the insulin receptor) activates phosphatidylinositol-3-kinase (PI3K) followed by Akt. Activated pAkt phosphorylates tuberous sclerosis complex-2 (TSC2), which blocks its GTPase-activating protein (GAP) activity. When not phosphorylated, TSC2 complexed with TSC1 functions as a GAP for Rheb, maintaining Rheb in an inactivated Rheb-GDP state. Activated Rheb (Rheb-guanosine triphosphate [GTP]) is therefore abundant when TSC1 or TSC2 is missing or defective, or when TSC2 is phosphorylated. Rheb GTP activates mTOR, in a manner that is potentiated by the availability of amino acids, phosphatidic acid, and adenosine triphosphate, and blocked by the absence of these substrates or the presence of sirolimus. Activated mTOR complexed with raptor phosphorylates downstream targets S6K and 4E-BP1. pS6K phosphorylates S6 and 4E-BP1 releases eIF4E, which together activate the cellular translational machinery and promote cell growth. S6 also feeds back to inhibit upstream signaling, which restrains cell growth and “malignant” cellular behavior. Activated mTOR complexed with rictor signals through a divergent pathway to control cytoskeletal dynamics and cell movement through Rho kinases. (Adapted from Kwiatkowski DJ: Rhebbing up mTOR: new insights on TSC1 and TSC2, and the pathogenesis of tuberous sclerosis. *Cancer Biol Ther* 2:471–476, 2003.)

Hamartin has no informative homologies with other proteins in the National Center for Biotechnology Information database, whereas tuberin has a domain with *GTPase-activating protein* (GAP) homology.³⁹

Until recently, little was known about the function of TSC proteins other than that they modulate cell growth. In 1999, it was reported that the enlarged eye cell phenotype of the mutant fruit fly, *Gigas*, was the result of genetic inactivation of the fly homologue for tuberin.⁴⁰ The loss of tuberin results in a defect in cell cycle control, which causes cells to repeat S phase without entering M phase. Several laboratories subsequently reported that tuberin and hamartin regulate signaling through the PI3K/PKB(Akt)/S6K pathway, which controls cellular size and proliferation.⁴¹⁻⁴³

Our understanding of the function and positioning of the TSC proteins in the Akt/S6K pathway has been a rapidly evolving process, and the available data to date are modeled

in [Figure 69-1](#). Tuberin and hamartin associate into a complex that functions as a master regulator for the kinase, mTOR, or mammalian target of rapamycin (sirolimus), through an intermediate G protein called Rheb.^{44,45} The intact tuberin/hamartin complex acts as a GAP for Rheb, maintaining the protein in an inactivated, nonphosphorylated state (Rheb-GDP). Phosphorylation of tuberin by Akt inactivates the GAP activity of the tuberin/hamartin complex, increases the abundance of Rheb-GTP, drives association of mTOR with raptor (and mLST8 and PRAS40, not shown) to form the mTORC1 complex, and results in phosphorylation and activation of downstream kinases mTOR, S6K, and the initiation factor *4E-binding protein* (4E-BP1). The association of mTOR with raptor (and mSIN1 and mLST8, not shown) to form mTORC2 results in activation of ROCK and rho kinase, cytoskeletal rearrangement, and cell movement.

truncating *TSC2* mutations associated with LOH in the abnormal lung and kidney tissue of patients with S-LAM.³⁵ Samples taken from the normal regions of lung and the kidney in those patients did not exhibit TSC mutations.⁴⁹ These findings were subsequently confirmed in 21 patients by Sato and associates,⁵¹ A single patient with S-LAM caused by *TSC1* mutations has been described to date.^{35,51,52} These data indicate that somatic mutations in either *TSC2* or *TSC1* alleles after conception cause S-LAM and result in defects or deficiency in tuberlin or hamartin. *TSC1* and *TSC2* mutations have both been described in TSC-LAM, although *TSC2* mutations are more common.^{20,53}

GENETIC EVIDENCE SUGGESTS THAT LYMPHANGIOLEIOMYOMATOSIS IS A METASTATIC NEOPLASM

Cornog and Enterline⁵ were the first to suggest that, despite their benign appearance, cells that make up the LAM lesion represent a clonal, neoplastic proliferation of smooth muscle cells. The demonstration of LOH in the lung, kidney, and lymph node lesions in patients with LAM indicated that Cornog and Enterline's suspicions regarding neoplasia and clonality were correct.⁵⁰ Carsillo and colleagues³⁵ further demonstrated that the mutations present in the cells of the kidney tumor and lung lesion of a given individual with S-LAM were identical, suggesting that they arise from a common precursor.

A model for LAM has been proposed in which the lung is infiltrated as a consequence of benign metastasis of LAM cells from a remote and, as yet unidentified, source such as the bone marrow, the lymphatic system,⁵⁴ the uterus,⁵⁵ or AMLs.⁵⁶ Reports of recurrence of LAM in the donor lung of patients with LAM who had undergone lung transplantation are also consistent with this metastatic theory⁵⁷⁻⁶⁰; in two cases, the source of lung metastases were proven to arise from the recipient by genetic and molecular techniques.^{60,61} These data contradicted earlier reports that the recurrent lesions were derived from donor cells,^{57,58} but in retrospect, the initial studies were limited by the spatial resolution that can be achieved with the immunohistochemical techniques used to colocalize cellular markers. Cells containing LOH for TSC genes have been isolated from the blood of patients with LAM,⁶² consistent with dissemination through the systemic circulation.

Other rare diseases that result from metastases of benign smooth muscle cells in women include leiomyomatosis peritonealis disseminata,⁶³ intravenous leiomyomatosis,⁶⁴ and benign metastasizing leiomyomatosis.⁶⁵ The metastatic theory of LAM suggests possible novel approaches for treatment based on preemptive removal of the source, once its identity is known.³¹

ROLE OF LYMPHANGIOGENESIS AND LYMPHATIC SPREAD IN DISSEMINATION OF LYMPHANGIOLEIOMYOMATOSIS

Approximately 30% of patients with LAM have axial abdominal or thoracic lymphadenopathy.⁶⁶ In some cases, LAM is restricted to the retroperitoneum, abdomen, or pelvis and is associated with normal lung parenchyma or only a very few lung cysts, consistent with regional spread from a subdiaphragmatic source.⁶⁷ Clusters of cells in the

chylous pleural fluid of patients with LAM were first described by Valensi⁶⁸ in 1973. Later, Itami and coworkers⁶⁹ demonstrated that the clusters originated in the dilated lymphatic system and were composed of alpha smooth muscle actin–positive spindle cells enveloped by a single layer of endothelial cells. They suggested that LAM cell clusters could be used diagnostically to obviate the need for biopsy in patients with chylous manifestations of LAM. Data from Japan provide additional evidence that a likely source and mechanism of spread of LAM may be through the lymphatic circulation.^{54,70,71} In a small autopsy series, Kumasaka and colleagues^{54,72} described the presence of LAM cell clusters enveloped by lymphatic endothelial cells budding from the walls of lymphatic vessels and in the lumen of lymphatic channels and the thoracic duct.

Induction of lymphangiogenesis appears to play an important role in this process, based on abundant expression of lymphatic endothelial markers such as *podoplanin* (D2-40), LYVE-1, *vascular endothelial growth factor* (VEGF) receptor 3 (VEGFR-3), VEGF-C, and VEGF-D.⁷² Several laboratories have reported that VEGF-D is elevated more than threefold to eightfold in the serum of patients with LAM, a finding that is useful for distinguishing LAM from other cystic lung diseases and for predicting response to therapy.⁷³⁻⁷⁹ LAM clusters are found in the lymphatic lumen, in regions between axial lymph nodes (retroperitoneal, mediastinal, and left venous angle) that are infiltrated with LAM cells, and in chylous fluids of patients with chylous ascites and chylothorax.^{54,72,73,80,81} LAM cell clusters enter the venous circulation at the insertion of the thoracic duct into the junction of the left internal jugular and subclavian veins and disseminate throughout the pulmonary capillary bed. LAM cell clusters impacted in the lung vasculature proliferate and invade, perhaps through a novel mechanism called “invasion-independent metastasis.”^{82,83}

ROLE OF ESTROGEN

Estrogen-containing drugs have been implicated in the worsening of LAM. Estrogen may play a role in LAM cell migration, infiltration, proliferation, or secretion of destructive proteases.^{33,84} Estrogen regulates the transcription of many genes, and there is some evidence that estrogen can modulate signaling through the Akt pathway.^{84,85} Estrogen-mediated activation of the ERK pathway promotes activation of the late response gene *FRA1*, which is associated with epithelial mesenchymal transition.⁸⁶ Akt activation, in turn, enhances the efficiency of *FRA1* translation through the phosphorylation of the S6K1-dependent eucaryotic translation factor, 4b. Estrogen was shown to promote pulmonary metastases and enhanced survival of *TSC2*-deficient cells in mice.⁸⁷ Collectively, these data suggest that targeting the E2-ERK pathway in combination with the mTORC1 pathway may be an effective combination therapy strategy for LAM.

MECHANISMS OF MATRIX REMODELING IN LYMPHANGIOLEIOMYOMATOSIS

Cystic destruction of the lung parenchyma causes progressive decline in lung function in patients with LAM, and proteases are believed to play a major role in the process.

In addition, multiple growth factors are abundant in LAM, which induce proliferation, suppress apoptosis and support fibrosis. Targeting the systems that promote proteolytic and fibroproliferative responses are possible therapeutic strategies for the future.

More information on matrix remodeling Akt pathway signaling is available online.

CLINICAL FEATURES

LAM usually presents during the reproductive years, with a mean age at the onset of symptoms in the early to mid-30s.^{8,9,14,100} Although new diagnoses of LAM have been reported in patients as young as 12 years,^{101,102} documented cases of the disease before menarche are rare. A number of reports in the literature describe women in whom the diagnosis was made after menopause and in the ninth decade of life.^{8,9,14,100,103-106} LAM does not appear to be smoking-related, because the majority of patients in the largest case series were nonsmokers.^{9,12,14}

Because LAM is rare and the symptoms are often nonspecific, the diagnosis is often delayed, with a mean interval between the onset of symptoms and diagnosis of 5 to 6 years.^{8,11,14,107} Initial incorrect diagnoses in these series typically included bronchial asthma, emphysema, chronic bronchitis, chronic obstructive pulmonary disease, sarcoidosis, diffuse panbronchiolitis (in Asia), and even idiopathic interstitial pneumonias including idiopathic pulmonary fibrosis.

In the patients reported by Urban and associates,¹⁴ exertional dyspnea and spontaneous pneumothorax were the initial symptoms in 49% and 46% of patients, respectively. During the course of the illness, dyspnea developed in 87% of patients, and pneumothorax developed in 68% of patients. The first pneumothorax precedes the diagnosis of LAM in 82% of patients; in fact, most patients have two pneumothoraces before the diagnosis is made.^{108,109} In patients with LAM who have a pneumothorax, the likelihood of an ipsilateral or contralateral recurrence is greater than 70%.^{7,11,14,109} Pneumothorax most likely results from the rupture of subpleural blebs, but whether the event is triggered by progressive degradation of connective tissue matrix or airflow obstruction and overdistention of distal air spaces, or both, is unclear.

Other signs and symptoms of LAM, which may be present at the onset or may develop during the course of the disease, include fatigue, cough, hemoptysis (rarely massive), chest pain, and symptoms related to reflux of chylous fluid into pleural (33% of patients) and extrapleural locations, such as the peritoneum (chylous ascites) or pericardium (chylopericardium), airway (chyloptysis), and genitourinary tract (chyluria and chylous metrorrhagia). Fistulous communication in the gut can result in protein-losing enteropathy. Chylous pulmonary parenchymal congestion was recently described in patients with LAM and should be considered in the differential of subacute worsening of oxygenation or shortness of breath.¹¹⁰ It is likely that the chylous complications of LAM result from obstruction of lymphatic channels due to infiltration by smooth muscle cells.

AMLs, unusual hamartomas composed of fat, smooth muscle, and abnormal blood vessels, may arise in virtually any location in the chest and abdomen but are most

common in the kidney (eFig. 69-1). About 29% to 33% of patients with S-LAM have renal AMLs, compared with about 88% to 93% of patients with TSC or TSC-LAM.^{20,28} AMLs are more commonly unilateral and solitary in patients with S-LAM, and more commonly bilateral and multiple in patients with TSC-LAM (see eFig. 69-1).⁶⁶ Blood vessels in AMLs are often tortuous and aneurysmal and are composed of cells with normal genotype and cells with TSC mutations.¹¹¹ Spontaneous hemorrhage into AMLs may produce severe flank or abdominal pain, acute hypotension, and/or anemia, occasionally in association with circulatory collapse. Renal cysts are seen occasionally in patients with LAM; in TSC-LAM, polycystic kidney disease may develop due to a contiguous gene deletion of *PKD1* which is immediately adjacent to *TSC2* on chromosome 16.¹¹²

Lymphangiomyomas are tumor-like masses characterized by smooth muscle (LAM cells) and endothelial proliferation of lymphatic vessels and lymph nodes in the mediastinum, retroperitoneum, and lung. Not uncommonly, LAM presents as retroperitoneal masses, including cystic lymphangiomyomas (eFig. 69-2) or lymph nodes with hypodense centers, which mimic necrotizing lymphomas, ovarian or renal cancers, or other malignancies.^{113,114}

There have been case reports of exacerbation of LAM associated with birth control pill use¹¹⁵ or during pregnancy.¹¹⁶⁻¹²⁰ In a group of 69 patients with sporadic LAM, pulmonary symptoms began during pregnancy in 9 of the 46 patients (20%) with a history of pregnancy before or at the time of diagnosis.¹⁴ In this same group, a marked exacerbation of previously diagnosed pulmonary LAM was observed in two (14%) patients during pregnancy.¹²¹ The effect of pregnancy or exogenous estrogen use on LAM has not been systematically studied.

PHYSICAL EXAMINATION

The physical examination in LAM is often nonspecific. Lung auscultation is usually uninformative but may reveal rhonchi or wheezing in some patients.^{9,11,14} Crackles are unusual and should raise suspicion for chylous pulmonary congestion. Clubbing is not a feature of LAM, despite being reported in 3% and 5% of patients in two larger case series.^{9,11} Physical examination may also reveal evidence of pleural effusion, ascites, or pneumothorax, if present. Careful dermatologic, ocular, and dental surveys should be performed for evidence of TSC, including facial angiofibromas, subungual fibromas, palpable dysplastic cutaneous lesions called shagreen patches, hypomelanotic macules including those with ash leaf or confetti configurations, retinal hamartomas, and dental pitting.¹⁶

IMAGING STUDIES

The chest radiograph in patients may appear relatively normal (eFig. 69-3), even late in the disease, or may suggest hyperinflation only. As the disease progresses, the chest radiograph often demonstrates diffuse, bilateral, and symmetric reticulonodular opacities (eFig. 69-4), cysts (eFig. 69-5), bullae, or a “honeycomb” or somewhat “pseudofibrotic” appearance (eFig. 69-6).^{9,14} Pleural effusion and pneumothorax (eFig. 69-7) may also be apparent (Fig.

The spectrum of metalloproteinases that are aberrantly expressed in LAM has not been fully characterized, but *matrix metalloproteinase* (MMP)-2 is the most abundant of those studied to date. Overexpression of MMP-1, MMP-9, MT1-MMP, and MMP-14 has also been reported,⁸⁸ and serum levels of MMP-9 are elevated in patients with LAM.⁸⁹ MMP-1, MMP-2, and MMP-9 are able to degrade elastin, consistent with the loss and degradation of elastic fibers seen in LAM.⁸⁸ Zhe and associates have proposed that increased expression of serum response factor may lead to MMP activation⁹⁰⁻⁹³ and down-regulation of *tissue inhibitor of metalloproteinase* (TIMP-3) in LAM cells,⁹⁰ leading to an imbalance of proteases and protease inhibitors. Abundant expression of cathepsin K has been reported in LAM, suggesting a possible pathogenic role of this protein in tissue destruction.⁹⁴

Basic fibroblast growth factor (bFGF) is a potent mitogenic factor for smooth muscle cells, myofibroblasts, and fibroblasts. LAM lesions have also been reported to contain abundant tryptase-positive mast cells, which express bFGF and receptors *Bek* (FGFR-2) and *Flg* (FGFR-1), as well as chymases, renin, angiotensin-converting enzyme, and angiotensin receptors type I and type II.^{95,96} *Insulin-like growth factors* (IGFs) are involved in normal pulmonary development and in the pathogenesis of smooth muscle cell proliferation. IGF-I, IGF-II, IGF-I receptor, *IGF-binding protein* (IGFBP)-1, IGFBP-2, IGFBP-4, IGFBP-5, and IGFBP-6 are expressed in lung tissue of patients with LAM.⁹⁷ Carelli and coworkers⁹⁸ showed that *TSC2*^{-/-} human smooth muscle cells derived from AMLs express the apoptosis inhibitor protein survivin when exposed to IGF-1. Transforming growth factor- β 1, a profibrotic cytokine, is enriched in highly cellular areas of the LAM lesion.⁹⁹

Figure 69-2 Sporadic LAM with chylothorax. Chest radiograph (A) and high-resolution CT (B) of a 40-year-old woman with sporadic LAM. Diffuse cystic changes and a right-sided chylothorax (arrows) are present.

69-2). Preservation of lung volumes in the presence of increased interstitial markings is a radiographic hallmark of LAM that helps distinguish it from most other interstitial lung diseases (see eFigs. 69-3A, 69-4, 69-5A, and 69-6A), in which alveolar septal and interstitial expansion tend to increase the lung's elastic recoil properties and decrease lung volumes.

The *high-resolution computed tomography* (HRCT) chest scan is much more sensitive than the chest radiograph in detecting cystic parenchymal disease and is almost always abnormal at the time of diagnosis, even when the chest radiograph and pulmonary function assessments are normal.^{9,11,14,122} The typical CT shows diffuse round, bilateral, thin-walled cysts of varying sizes ranging from 1 to 45 mm in diameter (see Fig. 69-2; see eFigs. 69-1C, 69-2C, 69-3B through D, 69-5B, 69-6B, and 69-7B).^{11,14} The numbers of cysts varies in LAM from a few (see eFig. 69-7B) to almost complete replacement of the normal lung tissue (see eFig. 69-5B). The profusion of cysts tends to be milder in patients with TSC-LAM than S-LAM, perhaps explained in part by ascertainment of patients with TSC-LAM earlier in the disease process by screening.¹²³

The morphology of the cysts is useful in differentiating LAM from other cystic lung diseases (Fig. 69-3). In *emphysema*, dilated airspaces often have internal structure, such as septae or a “centrilobular dot” consistent with a vessel, features virtually never seen in LAM. In addition, in emphysema, the borders of the lucent spaces are difficult to discern, whereas in LAM, cyst walls are thin but easily perceptible. *Langerhans cell histiocytosis* cysts (see eFig. 54-37) have thick walls and the cystic spaces are bizarre in shape. *Birt-Hogg-Dubé* (BHD) cysts tend to predominate in the lower lobes, while LAM cysts are distributed diffusely. *Lymphocytic interstitial pneumonia* cysts can closely resemble those of LAM, but are often larger, more varied in size, and bounded by eccentric vessels. Blinded expert radiologists can correctly identify LAM among a pool of CT scans consisting of a variety of other cystic lung diseases about 72% of the time.¹²⁴ Pleural effusions are seen on CT in 12% of patients with S-LAM and 6% of patients with TSC-LAM. Other CT

features include linear densities (29%), hilar or mediastinal lymphadenopathy (9%), pneumothorax, lymphangiomyomata (see eFig. 69-2), and thoracic duct dilation.^{11,14} Ground-glass opacities (12%) suggest the presence of interstitial edema due to lymphatic congestion (Fig. 69-4).

In patients with TSC, nodular densities on HRCT may represent *multifocal micronodular pneumocyte hyperplasia* (MMPH) made up of clusters of hyperplastic type II pneumocytes^{23,125,126} (Fig. 69-5; see eFig. 56-2). MMPH may be present in males or females with TSC in the presence or absence of LAM, but not in patients with S-LAM.¹²⁷ MMPH is not typically associated with physiologic or prognostic consequences, but one case of respiratory failure due to MMPH has been reported.¹²⁸

Chu and associates¹¹ reported that ventilation-perfusion scans were abnormal in 34 of 35 women with LAM. The most common abnormality was nonspecific diffuse heterogeneity, usually grossly matched. These authors also described an “unusual,” “speckling pattern” on the perfusion images in 74% of patients, consisting of “small, often peripheral collections of radioisotope.”

LAM and AML lesions do not typically exhibit increased uptake of ¹⁸F-fluorodeoxyglucose on PET scanning.^{129,130} Other neoplasms (or sources of inflammation) should therefore be considered in known or suspected LAM cases in which FDG-PET results are positive.¹²⁰

Abnormalities on abdominal imaging, such as renal AML (see eFig. 69-1A and B) and enlarged lymphatic structures, are also common in LAM (Figs. 69-6 and 69-7). Fat density within a renal mass is pathognomonic of AMLs (see eFig. 69-1A and B). AMLs are more prevalent and more frequently bilateral and large in patients with TSC-LAM than in patients with S-LAM, and AML size correlates with the prevalence of pulmonary cysts in patients with TSC.²⁰ Avila and associates¹²³ reported the results of CT imaging in 256 patients with S-LAM and 67 patients with TSC-LAM who were referred to the National Institutes of Health. Renal AMLs were present in 32% of patients with S-LAM and 93% of patients with TSC-LAM. Hepatic AMLs (see eFig. 69-1A) were present in 2% of patients with S-LAM and 33% of

Figure 69-3 LAM cystic lung disease mimics. **A**, Centrilobular emphysema—note lack of a true cyst wall and the presence of the centrilobular artery (arrowhead) with the cystic region. **B**, Pulmonary Langerhans cell histiocytosis—note “bizarre-shaped” cysts (arrowheads) and numerous nodules. **C**, Birt-Hogg-Dubé syndrome—note lower lobe predominance of cysts. Spontaneous pneumothorax (*) is present bilaterally. **D**, Lymphocytic interstitial pneumonia—the cysts in this disorder may closely simulate LAM, particularly when no other infiltrative parenchymal findings coexist. **E**, LAM, presented for comparison. Note the relatively uniform, thin-walled appearance of the cysts with normal-appearing intervening lung parenchyma. (Courtesy Michael Gotway, MD.)

Figure 69-4 Interstitial pulmonary edema due to lymphatic obstruction/congestion. In patients with cystic change seen on high-resolution CT that is otherwise typical for LAM, the ground-glass appearance (arrows), often together with chylous effusions, lymphadenopathy, and/or lymphangiomyomas, may be indicative of pulmonary lymphatic congestion due to chylous reflux. This entity should be considered in the differential of worsening dyspnea or hypoxemia and is amenable to treatment with sirolimus. Other considerations include bronchospasm, which is present in up to 20% of patients with LAM, and intrapulmonary shunts.

patients with TSC-LAM. Ascites was uncommon, seen in fewer than 10% of patients with LAM. Abdominal lymphangiomyomas (see eFig. 69-2B), often containing both cystic and solid components, were seen in 29% of patients with S-LAM and 9% of patients with TSC-LAM.

Central nervous system abnormalities, such as cortical or subependymal tubers and astrocytomas, are common in patients with TSC, including those with TSC-LAM, but are not found in women with S-LAM. Moss and associates¹³¹ reported that women with S-LAM and TSC-LAM may have an increased incidence of meningioma, but the significance of that finding has been challenged.¹³²

PULMONARY FUNCTION TESTING

Pulmonary function testing in patients with LAM may be normal or may reveal obstructive, restrictive, or mixed patterns, with obstructive physiology being the most common abnormality. Quality controlled lung function data were collected prospectively by the NHLBI Registry,²⁸ a 5-year study of patients with LAM in centers around the United States. Spirometry revealed obstructive changes in about 57% of patients and normal results in 34%.²⁸ Restriction, defined as a total lung capacity less than the lower limit of

Figure 69-6 Angiomyolipoma. Axial abdominal CT scans (**A** and **B**) and angiography (**C**) of a renal angiomyolipoma in a 16-year-old female with sporadic LAM. Note the tumor (arrow) in the right kidney. (**A** and **B**, Courtesy Dr. Shoji Samma, Nara Prefectural Nara Hospital, Japan.)

normal, was seen in 11%. Hyperinflation was unusual, present in about 6%. The average residual volume was 125% of predicted when measured by plethysmography, but was only 103% of predicted determined with gas dilution methods, suggesting significant air trapping in non-communicating airspaces. Approximately 25% of patients with obstructive physiology may demonstrate bronchodilator responsiveness.¹² The obstructive physiologic defect in LAM is primarily attributable to airflow obstruction and, to a lesser degree, to a modest increase in lung compliance.¹³³

The most common finding on initial pulmonary function testing in various case series was abnormal gas transfer, as assessed by the *diffusing capacity for carbon monoxide* (DL_{CO}), described in 82% to 97% of patients.^{8,9,11,14} It is not unusual

for DL_{CO} to be reduced out of proportion to *forced expiratory volume in 1 second* (FEV_1).¹² Reduction in DL_{CO} and increase in residual volume are generally considered to be the earliest physiologic manifestations of LAM.

Crausman and colleagues¹³⁴ studied the mechanism of exercise limitation in 16 patients with LAM. They concluded that poor exercise performance was primarily due to airflow obstruction and increased dead-space ventilation caused by pulmonary vascular disease or extensive cystic change. Cardiopulmonary exercise testing in a much larger cohort of patients with LAM revealed a reduced *maximal oxygen consumption* ($\dot{V}O_{2max}$) and anaerobic threshold in 217 patients.^{135,136} Exercise-induced hypoxemia was found even in patients who did not have resting abnormalities in

FEV₁ and DL_{CO}. In most patients, exercise was thought to be ventilation limited, owing to airflow obstruction and increased dead-space ventilation.

Disease progression is usually accompanied by a progressive obstructive ventilatory defect, and decline in FEV₁ is the most commonly used parameter to monitor disease progression. Although resting pulmonary hypertension appears to be unusual in LAM, pulmonary arterial pressure often rises with low levels of exercise, related in part to hypoxemia.¹³⁶ Zafar and colleagues¹³⁷ reported an increase in intraparenchymal shunts in dyspneic patients with LAM, which may contribute to resting and exercise hypoxemia.

Taveira-DaSilva and coworkers¹² correlated lung function testing with lung histology in 74 patients. They reported that a positive bronchodilator response was associated with a predominantly solid pattern of lung lesions as

opposed to a cystic pattern. They also found that the DL_{CO} correlated with the lung histology score, a quantification of the extent of involvement with cystic lesions and LAM cells. FEV₁ and DL_{CO} were the best predictors of $\dot{V}O_{2\max}$.

PATHOLOGY

Grossly, LAM lungs are enlarged and diffusely cystic, with dilated air spaces as large as several centimeters in diameter^{7,138} (Fig. 69-8). Microscopic examination of the lung reveals foci of smooth muscle cell infiltration of the lung parenchyma, airways, lymphatics, and blood vessels associated with areas of thin-walled cystic change. LAM lesions often contain an abundance of lymphatic channels, forming an anastomosing meshwork of slitlike spaces lined by endothelial cells. LAM cells generally expand interstitial spaces without violating tissue planes but have been observed to invade the airways, the pulmonary artery, the diaphragm, aorta, and retroperitoneal fat, to destroy bronchial cartilage and arteriolar walls, and to occlude the lumen of pulmonary arterioles.⁷

There are two major cell morphologies in the LAM lesion: small spindle-shaped cells and cuboidal epithelioid cells.¹³⁹ LAM cells stain positively for smooth muscle actin, vimentin, desmin, and, often, estrogen and progesterone receptors (Fig. 69-9). The cuboidal cells within LAM lesions also react with a monoclonal antibody called HMB-45, developed against the premelanosomal protein gp100, an enzyme in the melanogenesis pathway.¹³⁹ This immunohistochemical marker is very useful diagnostically, because other smooth muscle–predominant lesions in the lung do not react with the antibody.¹⁴⁰ The spindle-shaped cells of the LAM lesion are more frequently proliferating cell nuclear antigen–positive than the cuboidal cells, consistent with a

Figure 69-7 Abdominal CT of cystic lymphangiomyomas (arrows) and retroperitoneal lymphadenopathy in a patient with LAM.

proliferative phenotype.¹³⁹ Compared with cigar-shaped normal smooth muscle cells, spindle-shaped LAM cells contain less abundant cytoplasm and are less eosinophilic. Estrogen and progesterone receptors are also present in LAM lesions,^{141,142,142a} but not in adjacent normal lung tissue.¹⁴³ LAM lesions express lymphatic markers LYVE-1, PROX1, podoplanin and VEGFR-3.^{143a} The smooth muscle-like cells of AMLs are morphologically and immunohistochemically similar to LAM cells, including reactivity with antibodies directed against actin, desmin, vimentin, and HMB-45 as well as estrogen and progesterone receptors.^{144,145} Unlike the dilated air spaces in emphysema, the cystic spaces found in LAM may be partially lined with hyperplastic type II cells.¹⁴⁶

DIAGNOSIS

The diagnosis of LAM usually follows CT scanning of the chest, often triggered by one of four presentations: chronic dyspnea on exertion, new onset or recurrent pneumothoraces, chylous effusion, or incidental cysts found on scans of the chest, heart, or abdomen done for other reasons. When based on dyspnea, diagnoses such as obstructive pulmonary diseases (e.g., asthma or chronic bronchitis) are often erroneously made first, resulting in delays in the diagnosis of LAM for up to several years. The time to diagnosis is typically shorter following pneumothorax or chylous effusion, but most patients have more than one pneumothorax before the diagnosis is made.^{108,109} Cardiac and abdominal CT scans performed for other indications can detect cystic change in the lung and lead to performance of a dedicated chest CT and a diagnosis of LAM.

CLINICAL DIAGNOSIS

In the proper clinical context, a confident, clinical diagnosis of LAM may be established based on radiographic

findings.¹⁴⁷ For instance, classic LAM cystic changes on HRCT of the lung along with a chylothorax documented by thoracentesis or CT evidence of fat-containing renal masses consistent with AMLs establishes the diagnosis with a high degree of certainty. There are rare exceptions, however, because lymphomas can present with pulmonary cystic change and chylothorax, and Birt-Hogg-Dubé (BHD) syndrome (see Fig. 69-3) can present with pulmonary cystic change, and AMLs, albeit rarely.¹⁴⁸ Pulmonary cystic change in a nonsmoking woman with TSC is consistent with LAM and does not usually require biopsy. In smoking patients with or without TSC, the diagnoses of pulmonary emphysema and Langerhans cell histiocytosis¹⁴⁹ (see Fig. 69-3; see eFig. 54-37) must be seriously considered. Serologies for Sjögren syndrome antibody A (SS-A) and B (SS-B) should be obtained to investigate follicular bronchiolitis and lymphocytic interstitial pneumonitis; alpha₁ antitrypsin should be measured to exclude emphysema caused by antitrypsin deficiency.¹⁵⁰ Serum VEGF-D is elevated threefold to eightfold in patients with LAM,⁷¹ but not in patients with pulmonary emphysema, Langerhans cell histiocytosis, lymphangiomatosis, or BHD and is useful in differentiating LAM from these disorders.⁷⁴ A serum level of VEGF-D of at least 800 pg/mL in a patient with typical cystic change on HRCT establishes the diagnosis of LAM with a sensitivity and specificity of 60% and 100%, respectively.⁷⁶

To aid in diagnosis of LAM, a dedicated CT of the abdomen may be obtained to screen for AMLs, lymphangiomomas, uterine masses, and chylous ascites. Renal AMLs can be identified radiographically based on the presence of fat (see eFigs. 69-1A and B); biopsy may be required to rule out renal cell carcinoma in the rare cases in which renal masses are solid appearing and do not contain fat.

DIFFERENTIAL DIAGNOSIS

The primary differential diagnoses in patients with a smoking history include Langerhans cell histiocytosis and

pulmonary emphysema. The morphology of the cysts can be helpful in differentiating these disorders from LAM; in emphysema (see Fig. 69-3), the cysts are devoid of distinct walls and, in Langerhans cell histiocytosis (see Fig. 69-3; see eFig. 54-37), the cysts are thicker walled, mid and upper lung zone predominant, and more irregularly shaped.¹²⁴ Diffuse subcentimeter nodular changes are often present in Langerhans cell histiocytosis (see eFig. 54-38), but can also be seen in TSC-LAM, where they usually represent MMPH.¹²⁷ Other cystic lung diseases that can mimic LAM and that should also be considered include Sjögren syndrome,¹⁵¹ Castleman disease, follicular bronchiolitis and lymphocytic interstitial pneumonitis (see Fig. 69-3), *Pneumocystis jirovecii* pneumonia (see eFigs. 90-14 and 90-15), recurrent respiratory papillomatosis (see eFigs. 54-29 through 54-32), hyper IgE syndrome, hypersensitivity pneumonitis (eFig. 69-8),¹⁵² amyloidosis (see eFig. 54-35), lymphoma, light chain deposition disease,¹⁵³ and bronchopulmonary dysplasia/barotrauma.^{150,154} Note that a few scattered thin-walled cysts may normally be encountered on HRCT studies, particularly in older individuals.¹⁵⁵ Recently, diffuse thin-walled cysts seen on HRCT have been described in a small number of patients with various small airway obstructive disorders, including asthma.¹⁵⁶ Thin-walled cystic lung lesions can also be associated with metastatic genitourinary neoplasms (eFig. 69-9) including endometrial stromal cell sarcoma,¹⁵⁷ low-grade leiomyosarcomas and angiosarcomas (eFig. 69-10), cystic fibrohistiocytic tumor, and cystic benign metastasizing leiomyoma (eFig. 69-11).⁶⁵

BHD syndrome¹⁵⁸ can be difficult to distinguish from LAM. BHD is a rare tumor suppressor syndrome associated with spontaneous pneumothorax, skin lesions, bland, peripheral and subpleural pulmonary cysts devoid of smooth muscle infiltration (see Fig. 69-3; Fig. 69-10), and inherited renal neoplasms. Mutations in the folliculin gene (*FLCN*) cause defects or deficiency in a protein of unknown function called *folliculin* and result in BHD syndromes of renal tumors, lung cysts, and skin lesions, or familial spontaneous pneumothorax.^{159,160} It appears that BHD is also associated with aberrant signaling through the Akt pathway, but the loss of regulation is upstream of mTOR.

Chylous diseases that involve the thorax, including lymphangiomatosis, lymphangiectasis, and lymphatic dysplasia,¹⁶¹⁻¹⁶⁴ may also be confused with LAM, although they do not typically produce cystic change in the lung.

LUNG BIOPSY

The diagnosis of LAM is most definitively established by lung biopsy. HMB-45 staining is highly specific for LAM and can be used to differentiate LAM from other causes of smooth muscle proliferation in the lung including idiopathic pulmonary fibrosis, benign metastasizing leiomyoma, and leiomyosarcoma. Bronchoscopic diagnosis, using transbronchial biopsies with appropriate immunohistochemical staining and expert interpretation, represent a viable alternative to surgical biopsy in some cases.¹⁶⁵ Recent small series suggest the yield of transbronchial biopsy may exceed 60% and, although the numbers of patients studied in these cohorts precludes definite conclusions regarding safety, there were few complications reported.¹⁶⁶⁻¹⁶⁹ In one large series from China, transbronchial biopsy was used to make the diagnosis in 49 of 97 patients with pathologic confirmation.¹⁶⁹ Video-assisted thoracoscopic lung biopsy remains the “gold standard” for making the diagnosis of LAM, although with proper application of diagnostic guidelines, VEGF-D testing, abdominal imaging, and transbronchial biopsy, fewer than 15% to 20% of patients should require a surgical approach. A proposed algorithm for the diagnostic approach to a patient with suspected LAM is presented (Fig. 69-11). Clarity regarding the diagnosis of LAM facilitates discussions regarding life planning, pregnancy, birth control, pneumothorax management, and candidacy for trials, and is increasingly important in the era of effective but side-effect prone therapies.

TRIALS AND TREATMENT

The remarkable gender restriction in LAM, although unexplained, has provided the rationale for the empirical antiestrogen strategies that have dominated the approach to LAM for the past several decades. The results have been generally disappointing and, because proper trials with hormonal therapies have never been conducted, there remain no proven therapies for LAM based on antagonism of estrogen action. Bilateral oophorectomy has not been demonstrated to slow the rate of decline in lung function in LAM.^{8,9,14} Enthusiasm for the use of progesterone, which became the standard of care following a single positive outcome published in a case report in 1987,¹⁰⁰ has likewise waned over

Figure 69-10 Birt-Hogg-Dubé syndrome. HRCT (A) and histopathologic (B; H&E staining) presentation of the lung cysts. This 58-year-old patient had repeated bilateral pneumothoraces and a family history of pneumothorax in a brother, son, and daughter. In the cyst wall, there is a lack of smooth muscle infiltration. (Courtesy Dr. Takashi Ogura, Kanagawa Cardiovascular and Respiratory Center, Kanagawa, Japan; and Tamiko Takemura, Japanese Red Cross Medical Center, Tokyo, Japan.)

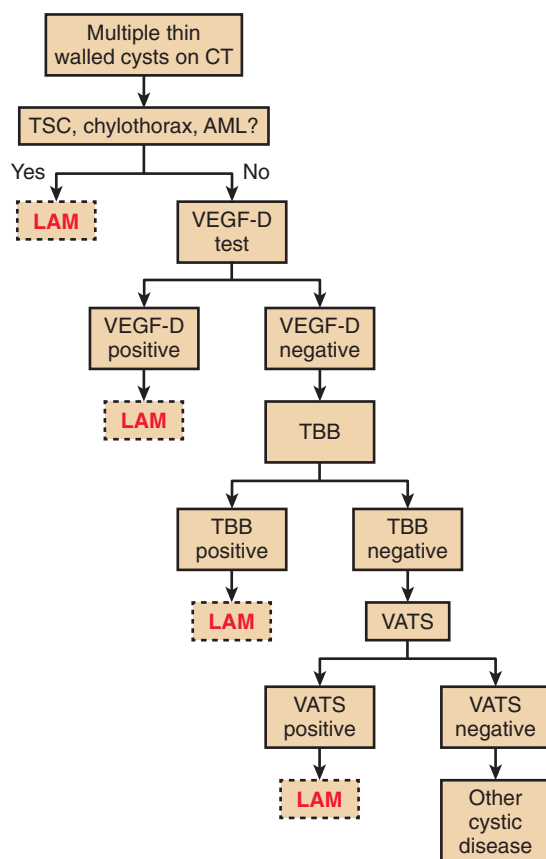

Figure 69-11 Proposed diagnostic algorithm for LAM. LAM should be considered in the differential of thin-walled multicystic lung disease. In a patient with typical CT changes, a confident clinical diagnosis of LAM can be made if tuberous sclerosis, chylothorax, a lymphangiomyoma, or an angiomyolipoma are present. For patients without these features, a serum VEGF-D level greater than 800 pg/mL is also diagnostic for LAM. If VEGF-D is negative, transbronchial biopsy, cytologic examination of pleural fluid, or thin needle biopsy of abdominal or thoracic masses can be useful for obtaining a pathologic diagnosis without surgery. Video-assisted thoracoscopic biopsy can be employed if the aforementioned approaches are uninformative, and will distinguish LAM from other mimics including emphysema, Langerhans cell histiocytosis, and lymphocytic interstitial pneumonitis/follicular bronchiolitis. AML, angiomyolipoma; TBB, transbronchial biopsy; TSC, tuberous sclerosis complex; VATS, video-assisted thoracoscopic surgery; VEGF-D, vascular endothelial growth factor D.

time. In a retrospective study of 275 patients, Taveira-DaSilva and associates¹⁰⁷ found that progesterone treatment failed to slow the decline in FEV₁. In fact, in that study, intramuscular or oral progesterone therapy was associated with an accelerated rate of decline in DL_{CO} compared with that in untreated patients. In another study, the rate of decline in FEV₁ and DL_{CO} was no different in patients treated with the gonadotropin-releasing hormone agonist triptorelin for 3 years than in a well-characterized cohort of historical controls.¹⁷⁰ Other case series of gonadotropin-releasing hormone agonist treatment have yielded conflicting results.¹⁷¹⁻¹⁷³ Use of gonadotropin-releasing hormone agonist is therefore not routinely recommended, except perhaps in patients who suffer recurrent, cyclical shortness of breath, chest discomfort, or pneumothoraces during menstruation. There is no proven role for corticosteroids, immunomodulatory cytotoxic agents, or ovarian irradiation in the treatment of LAM.

SIROLIMUS

Sirolimus had been shown to silence S6 phosphorylation and to induce apoptosis, necrosis, and regression of renal cystadenomas in TSC mutant rats and of hepatic tumors of TSC heterozygous null mice.^{174,175} Goncharova and colleagues¹⁷⁶ reported abundant S6 phosphorylation and unregulated cell proliferation in LAM cells isolated from explanted LAM lungs harvested at lung transplant. They further demonstrated that sirolimus blocked the hyperphosphorylation of S6 in cultured LAM cells and restored orderly cell growth.

The discovery of the importance of the mTOR pathway in LAM and preclinical studies in TSC animal models formed the basis for phase I/II trials of sirolimus in patients with tuberous sclerosis and LAM (*Cincinnati Angiomyolipoma Sirolimus Trial* [CAST]; NCT00457964).¹⁷⁷ In this open-label study, 25 patients with AMLs, including 6 patients with S-LAM, 12 with TSC-LAM, and 7 with TSC alone, were treated for 1 year with sirolimus and followed with serial magnetic resonance imaging studies of the kidneys, chest CT scans, and pulmonary function tests. Of the 20 patients still enrolled at 1 year, AML volume shrank by an average of 47%; of the 11 patients with LAM still enrolled at 1 year, the FEV₁ and forced vital capacity (FVC) increased by 118 mL and 390 mL, respectively. The residual volume fell by 440 mL, and cyst volume percent, a measurement of the fraction of the pulmonary parenchyma occupied by cysts, tended to decline on therapy.¹⁷⁸ Parameters that did not change included total lung capacity, 6-minute walk distance, and DL_{CO}. There were a number of adverse events while patients were taking the study agent, including mouth ulcers, cholesterol elevations, and hospitalizations for pneumonia, diarrhea, cellulitis, pyelonephritis, palpitations, and mucositis.

In the second year of the trial, patients were observed off the study agent at 6-month intervals. At the 2-year point, the average AML volume had increased again to 86% of baseline, although in 25% of patients, AML size remained below 70% of baseline; FEV₁ and FVC had declined at rates that are generally consistent with those of untreated patients with LAM,¹⁷⁹ but remained 62 mL and 364 mL above baseline, respectively; residual volume remained 333 mL below baseline, indicative of durable reduction in gas trapping. Similar results were seen in subsequent trials.^{180,181}

On the basis of the unexpected lung function response in the 11 patients with LAM, and a higher than expected rate of adverse events, a pivotal trial was designed to determine the risks and benefits of sirolimus in patients with LAM. The *Multicenter International LAM Efficacy of Sirolimus* (MILES) trial was a randomized, double-blind, controlled trial of sirolimus in 89 women with LAM and abnormal lung function (FEV₁ < 70% predicted).¹⁸² During the 1-year treatment period, lung function (FEV₁) stabilized on sirolimus, while declining by about 11% in the placebo group. Sirolimus also improved some measures of quality of lung and functional performance. In the observation year off therapy, lung function decline resumed in the sirolimus group and paralleled that in the placebo group. At baseline, serum VEGF-D was elevated by more than fivefold (relative to healthy

volunteers⁷³) in both groups. VEGF-D remained stable in the placebo group but, in the sirolimus group, VEGF-D decreased by more than 50%. When sirolimus was withdrawn, VEGF-D increased toward baseline again.⁷⁵ The sirolimus-induced decreases in VEGF-D are intriguing in light of the strong lymphangiogenic phenotype observed in LAM and marked improvement in chylous effusions and lymphangiomyoma volume seen in patients with LAM with lymphatic involvement.¹⁸³ Adverse events were common during the treatment period and were more prevalent in the sirolimus group. There was no increase in risk of infection, however, and the frequency of serious adverse events was balanced between the groups.

Collectively, the data suggest sirolimus therapy stabilizes lung function and improves some measures of quality of life in patients with LAM. The fact that decline resumes when the drug is withdrawn indicates that the therapy is suppressive and does not result in durable remission. One explanation for the beneficial but transient effects on lung function and tumor volume seen in CAST, MILES, and other trials is that the drug may shrink cells, attenuate tumor cell infiltration, or inhibit proliferation within the organs, but does not induce apoptosis of LAM cells. It is possible that mTOR inhibitors must be given continuously to maintain cellular homeostasis and avoid AML regrowth and lung function decline; indeed, there is early evidence of sustained benefit from longer-term therapy.¹⁸⁴

GENERAL RECOMMENDATIONS—TREATMENT AND MANAGEMENT
